LIST OF CONTRIBUTORS TO VOL. XLI.

Abbe, Dr. Robert, New York.
Abbott, Dr. George E., New York.
Adams, Dr. F. J., Great Falls, Mont.
Alexander, Dr. C. M., Coleman, Tex.
Allen, Dr. Charles W., New York.
Allport, Dr. Frank, Minneapolis, Minn.
Amidon, Dr. R. W., New York.
Arnold, Dr. L. W., Florence, Ala.
Ashmead, Dr. Albert S., New York.
Aulde, Dr. John, Philadelphia, Pa.

Baker, Dr. C. O., Auburn, N. Y.
Bartlett, Dr. O. L., Rockland, Me.
Baruch, Dr. Simon, New York.
Bates, Dr. W. H., New York.
Bauer, Dr. Joseph L., St. Louis, Mo.
Beach, Dr. Wooster, New York.
Beck, Dr. Carl, Chicago, Ill.
Belt, Dr. A. M., Baltimore, Md.
Benedict, Dr. Samuel C., Athens, Ga.
Berg, Dr. Henry W., New York.
Berkeley, Dr. Henry J., Baltimore, Md.
Bevill, Dr. Cheves, Winfield, Ark.
Bicknell, Dr. Robert C., Murfreesboro, Tenn.
Biggar, Dr. A. H. F., Cleveland, O.
Bishop, Dr. H. D., Cleveland, O.
Black, Dr. J. F., Halifax, N. S.
Bodenhamer, Dr. William, New York.
Brannan Dr. John Winters, New York.
Bremner, Dr. W. W., New York.
Bridges, Dr. W. O., Omaha, Neb.
Brown, Dr. Edward J., Minneapolis, Minn.
Brush, Dr. Arthur C., Brooklyn, N. Y.
Bryson, Dr. Louise Fiske, New York.
Buchanan, Dr. J. R., Kansas City, Mo.
Bulkley, Dr. L. Duncan, New York.
Bull, Dr. Charles Stedman, New York.
Burnham, Dr. G. Herbert, Toronto, Canada.
Burns, Dr. Dawson, London, England.
Burrall, Dr. F. A., New York.
Burton, Dr. Augustus J., New York.

Carson, Dr. Edwin, San Diego, Cal.
Chambers, Dr. Talbot R., East Orange, N. J.
Chapman, Dr. H. W., Whitehall, Ill.
Chappell, Dr. Walter F., New York.
Cheesman, Dr. Hobart, New York.
Cheesman, Dr. Timothy Matlack, New York.
Claiborne, Dr. John Herbert, Jr., Clarke County, Va.
Clements, Dr. George Place, New York.
Collins, Dr. Joseph, New York.
Crane, Dr. Augustin A., Hawaii.
Crow, Dr. J. J., Carrollton, Ill.
Culver, Dr. Everett M., New York.

Dana, Dr. Charles L., New York.
Dawbarn, Dr. Robert H. M., New York.
Déclat, Dr., Nice, France.
Dennis, Dr. Frederic S., New York.
Dessar, Dr. Leonard A., New York.
Douglas, Dr. Richard, Nashville, Tenn.
Dowd, Dr. Charles N., New York.

MUNDÉ'S CASE OF SPONTANEOUS EXPULSION OF A SUBMUCOUS FIBROMA FROM THE UTERUS AND VAGINA

LINDNER EDDY & CLARK LITH N.Y.

[TAKEN FROM A TREATISE ON MEDICAL AND SURGICAL GYNÆCOLOGY BY S. POZZI, M.D., NOW IN PRESS BY WM. WOOD & CO.]

SPONTANEOUS EXPULSION OF UTERINE FIBROIDS. WITH CHROMO-LITHOGRAPHIC ILLUSTRATION.

(FROM POZZI'S GYNECOLOGY.)

"THE natural evolution of a fibroma tends toward its expulsion from the uterine walls, either externally or into the peritoneal cavity, and this effort is shown by the pedicles which are produced in these two directions. Although such cases are rare, still at times we observe the accouchement of a polyp under the influence of strong uterine contractions with rupture of the pedicle. The same thing may occur from the weight of the tumor alone and the thinning of the pedicle. In these conditions an effort of defecation or of vomiting suffices to expel the polyp. The rupture of the capsule of a submucous fibroma may produce its spontaneous enucleation, preceded by a period of pains and hemorrhage, or suddenly after some effort, or while under examination; it has sometimes followed labor and the consecutive contraction of the uterus.

"An analogous process to that which causes the rupture of the pedicle of a submucous polyp may also liberate a fibroma which is subserous and pedicled. The tumor then remains grafted to some point where it has formed adhesions, or lies free in the peritoneum and undergoes a kind of mummification.

"Another and more serious mode of spontaneous extrusion is preceded by the sloughing of the tumor, the sphacelated portions tending to escape outwardly; at times this takes place toward the uterine cavity, and all may go well, despite the danger of infection. Or there may be perforation of some neighboring organ, as the bladder, the recto-vaginal pouch, or the abdominal wall; the two former almost always causing death, the latter sometimes ending in recovery."

The plate accompanying this extract shows clearly the form, color, and size of a submucous fibroid which was expelled by a woman forty-nine years of age, who had had one child twenty eight years before. For several weeks she had complained of "falling of the womb," and at the time of expulsion she had felt something protrude from the vulva after making a sudden movement while standing. At the same time there was pain in the abdomen and an escape of blood from the vagina. An examination by Dr. Mundé disclosed the condition shown in the accompanying chromo-lithographic frontispiece. There had been a spontaneous expulsion of a submucous fibroma with partial inversion of the uterus. The tumor was rapidly detached with the fingers, the uterus easily replaced, and its cavity and the vagina packed with iodoform gauze. Recovery was uneventful.

Interesting points in the case were the rapidity with which the protrusion occurred, the absence of excessive hemorrhage and pain, and the obscurity of the diagnosis caused by the excessive fatness of the patient. Her abdominal walls were so thick that, even when completely relaxed by anæsthesia, it was impossible to distinguish the cup shaped depression over the uterus which is characteristic of inversion.

CONSIDERATIONS UPON MEDICAL HEMORRHAGE SURGICALLY TREATED; WITH A SUCCESSFUL CASE, BY A NEW TECHNIQUE, OF SALINE INFUSION FOR SEVERE HEMORRHAGE.[1]

BY ROBERT H. M. DAWBARN, M.D.,

PROFESSOR OF OPERATIVE SURGERY AND SURGICAL ANATOMY, NEW YORK POLYCLINIC.

"Friendship's blind service, in the hour of need,
Wipes the pale face, and lets the victim bleed.
Science must stop to reason and explain;
Art claps his finger on the streaming vein!"

THUS sings our sweetest singer. But what shall Art do when that vein is out of safe reach of his finger? What, in cases of apoplexy, hæmoptysis, wounds of the lung, hæmatemesis? Who is there that feels even a moderate amount of satisfaction with our success in checking bleeding where the broken vessel is not amenable to direct pressure or the artery-clamp?

The drugs we use—some of us—are legion. They range from ergot to gallic acid; from turpentine to lead; and yet we have a very strong feeling that our efforts along this line are commonly of little avail, and that other and natural causes, mainly, effect the cure, if bleeding ceases.

The very fact that the list of remedies at our command, and recommended by standard authorities as of some use, is so long a one, of itself goes to show their inefficacy.

Dr. Loomis's opinion in a matter of bleeding from the lungs is one which would be, I think, accepted with respect.

His "Text-book of Practical Medicine," eighth edition, p. 95, says: "It has never seemed to me that styptics or astringents have any control over bronchial hemorrhages, but aconite and opium are the two remedies upon which I rely. When the pulse is full and strong I use aconite; when it is weak, I employ morphia hypodermatically."

The really valuable means, concerning which the present paper is in part to treat, Dr. Loomis does not even mention.

As to aconite, so far as it is of use at all, it is by bleeding the patient into his own veins, so to speak; and has hence been called the "vegetable lancet." This idea in a much more efficient form is just what I propose to advocate. Regarding morphine, by slowing the breathing it renders the pulmonary circulation rather less active, and it also causes mental quietude and calm. But that is all. After a time nature causes a coagulum at the mouth of the bleeding vessel, and to aid this our drugs do very little.

During eight to ten years past I have for purely logical reasons been urging upon my students a different line of treatment in these cases—cases, I mean, of dangerous and yet unreachable bleeding anywhere.

This plan is simply to collect a great portion of the blood elsewhere than at the bleeding point, until time has been given for a firm clot to form—say an hour or so—and then slowly allow it to re-enter the general circulation.

[1] Read at a meeting of the Surgical Section of the New York Academy of Medicine, held November 9, 1891; also read in major part at the Annual Meeting of the Orange County Medical Society of New York

It is plain that this sequestration, especially if carried to the extent of causing a feeling of faintness, must diminish the blood-pressure at the bleeding point and thus conduce to clotting.

The experience which has been gained by actual practice of this plan during these years has added to my confidence in what seems almost a self-evident proposition. The plan is nothing new, I need hardly say; but devised in a day when, as to scientific knowledge regarding the circulation, the margin was wider than the text thereof, it seems not to have appealed strongly to the common-sense of the fathers in medicine. So far as I can discover it was not vigorously and faithfully tried, and was allowed to lapse. Instead, in those days, bleeding was done to check bleeding. For instance, it was at one time standard, in hemorrhage from a wounded lung (in addition to tamponnage) to bleed to faintness. The idea is similar, of course, to that now under discussion, and is perfectly sound in theory; only, the patient would presently need that lost blood to avoid dangerous shock and to aid recuperation of strength. A *temporary* bleeding, into his own veins, so to speak, would have been wiser.

Herein the Spanish windlass is our friend. That is, a towel or handkerchief is knotted loosely around the limb (or, if need be, the same method on all four limbs) at the junction with the body; and by twisting this with a stick blood is prevented returning to the trunk. In consequence the limb swells visibly. The arterial circulation is not so easily shut off; nor, of course, do we wish it to be. Hence we avoid stopping the pulse on the distal side of our windlass.

That such local stagnation of circulation is not free from danger in careless hands is granted. The limbs should be watched and kept well warmed; the constrictions should not too long be maintained lest gangrene result. This, like other serious measures in medicine, is to be advised simply as the lesser evil, and where death threatens from a severe hemorrhage not otherwise controllable.

There are certain persons born with what Oliver Wendell Holmes calls a "squinting brain." The proposition that the sum of seven and five is twelve they regard with suspicion. To them it seems eleven. Once in a while, by trying and proving everything, and taking nothing at all for granted, they really do upset some alleged fact upon which men have builded. Then their seven and five becomes that "little leaven which leaveneth the whole lump."

Such a doubting Thomas surprised me a few months ago when I was discussing these matters with him. I had been speculating upon the possible outcome, had the greatest pulpit orator of this age, when stricken with apoplexy, been promptly Spanish-windlassed, instead of being treated after the sugar-pellet method. I thought it quite possible not only that death might have been averted, but that a small brain clot, instead of a huge one, might have resulted; and the patient, surviving this slight and partial stroke, might have given the world a further period of brilliant work.

Here the gentleman with the mental squint observed that he hardly thought so. Indeed, upon reflection, he thought the plan suggested would be harmful. For by diminishing, as it would do, the amount of blood in the brain-vessels (by collecting it elsewhere in the body), the pressure outside those vessels would be lessened. Hence there would be less resistance, within the skull cavity to a big clot forming than otherwise would be the case. He thought, therefore, that hereafter he would have his apoplectic patients at once placed with the head lower than the trunk; for the quicker the head filled with blood, distending its vessels, the less space there would be for a clot to form in the brain outside them, and hence the more resistance to the outflow from the broken artery which would cause that clot!

In order to settle the point thus raised I wrote to Dr. William Gilman Thompson, who is very good-natured, a classmate of mine, and Professor of Physiology in the University of New York. Dr. Thompson's reply I will read you, by his permission:

"March 18, 1891.

"My Dear Dawbarn: I am much interested in your discussion regarding apoplexy, for I have recently been repeating some experiments upon intra-cranial pressure which I first saw in the Hoagland Laboratory a year or more ago.

"I. The normal blood-pressure in a dog's carotid supports a column of water about seven and a half or eight feet high. If the dog's skull be trephined, and a cork perforated by a small glass tube be carefully fitted into the trephined opening, water-pressure may be applied to any desired extent through the tube over the surface of the brain. No effects are noticed until such pressure becomes greater than the carotid pressure; *i.e.*, greater than eight feet of water. When this limit is passed the animal has convulsions, at first unilateral, affecting the legs of the side opposite the tube, then becoming general, until death is imminent from spasm of the diaphragm.

"Reducing the pressure is followed by immediate relief. By raising and lowering the pressure-bottle, convulsions may be produced and controlled *ad lib.*

"Remove the cork, and for several minutes the cortical vessels appear excessively anæmic. Then follows intense congestion, so great as to cause considerable hernia of the brain through the opening. It would be interesting indeed to apply windlasses in various situations, and note the effect while the above experiments were being performed.

"II. *Strapping the large veins in the extremities to prevent venous return, during pulmonary hemorrhage, has undoubted and immediate effect in lessening that hemorrhage. I have often verified this.*[1]

"III. Such procedure would doubtless tend to lessen extra-vascular cerebral pressure, but it would simultaneously lessen the intra-vascular pressure, and the latter would be affected to a greater degree, and more promptly, I should think, tending to give the hemorrhagic blood time to clot.

"The reason for this would be that the extra vascular pressure would be dependent somewhat upon conditions of absorption and osmosis, which would act more slowly than the almost instantaneous effect of withdrawing blood from the heart by damming it back in the extremities.

"Even ligating the carotids or the vertebral arteries has no very decided effect upon the quantity (and hence the pressure) of the ventricular fluid, or the amount of fluid contained in any of the cerebral tissues; while, of course, the pulsations of the brain cease and the intra vascular cerebral pressure falls.

"I should think, in conclusion, decidedly, that the very worst thing one could do in a case of apoplexy would be to increase, in any manner, the intra-vascular pressure.

"Sincerely yours,

"W. Gilman Thompson."

Such testimony as this no man can ignore.

I do not say that we should utterly discard the use of drugs in such cases; but would formulate my position in this wise: Whenever there is bleeding acute enough to threaten life, and not within reach of direct pressure nor of the artery-clamp, our main reliance should be the tourniquet or windlass, generally placed upon all the limbs.

I need hardly say that promptitude and the ounce of prevention may here save a pound of blood. Given a case where bleeding from the lungs or stomach has already occurred; or given a patient where family history, atheroma, high living, and attacks of cerebral congestion (perhaps with one or two slight strokes already sustained) point to apoplexy as the probable end of the story, we should make it a rule to show the relatives, privately, how to make and use the windlass. As to apoplexy, we should say to them: "If ever Mr. A—— becomes sud-

[1] Italics mine.—R. H. M. D.

denly unconscious, then, unless his face is pale and his pulse weak, put on the windlass instantly, tightly enough to make the limbs swell. Do this even before you send for the nearest doctor. Do not leave these bands on longer than an hour."

As a matter of collateral interest I may remark that in pulmonary œdema, suddenly developed by cardiac exhaustion from any cause, the windlass on the extremities offers, I believe, our speediest means of relief to the heart, tiding over a critical period until by free stimulation this organ can be made to resume efficient work. Valuable as is cupping in pulmonary œdema, the windlass is much more so, and for reasons which are obvious upon reflection.

In the remainder of this paper let us discuss briefly the question of saline infusion as a supportive means after checking an alarming hemorrhage.

I firmly believe that many a life is now lost in private practice because after severe post-partal or other bleeding has been controlled, the family doctor has not had the nerve, or the experience, or the appliances thought necessary to accomplish infusion; and the remaining amount of circulating medium being not enough, the patient succumbs.

And I have an abiding hope and trust that a plan of which I am about to speak—an exceedingly simple plan—may be the means of so popularizing saline infusion that it will be used wherever a sharp bleeding has occurred, even though life be not actually imperilled thereby.

But first it may be well to remark that the day of transfusion (either mediate or immediate), as distinguished from infusion, is past. That is to say, we now know that as good if not better results are reached by injecting warm saline-alkaline water as by transfusing blood. Aside from the obvious dangers—clotting, with embolism, sepsis, etc.—attendant upon the use of any kind of blood, we now know that blood-cells other than the human are broken down and disintegrated almost at once within the human body; and in consequence a great mass of detritus is thrown upon the organs having charge of metabolism of tissue, threatening to overwhelm them with work. Even human blood-cells are probably always so destroyed, although more slowly, when transferred into another body than that which gave them birth.

What seems needed is only some unirritating fluid supplying the lacking volume within the heart and vessels.

That is, to give to the heart a sufficient bulk of some harmless current running through its chambers to excite systolic action. If this is done, and done promptly, before the patient suffers too much from the shock caused by sudden and extreme anæmia, it is wonderful how large a loss of blood may be survived, and how rapidly, as if by magic, nature supplies multitudes of new red blood-cells to replace those lost.

As emphasizing these points, the following quotation from an eminent authority will be of interest:[1]

"After the greatest losses of blood in animals, a sufficient number of red corpuscles always remain in the circulation to carry on respiration, provided that the circulation is maintained. In animals, after the loss of half or two-thirds of the total quantity of blood in the body, the number of corpuscles per cubic millimetre may be found as high as 3,000,000 or 4,000,000. The absolute loss is great, but the relative loss is slight and is of little importance. The animal's health is in no way affected injuriously by the loss. . . . In man the loss of blood can never be so great as in animals. Syncope occurs earlier. Transfusion of blood is therefore never required for the purpose of supplying red corpuscles to carry on respiration after sudden loss of blood in a patient previously healthy. The immediate source of danger in such cases is not the want of red corpuscles but the disturbance of the relation between the vascular system and its contents. . . .

"It is remarkable how slight the disturbance in respiration may be in cases, for example, of pernicious anæmia in which the red corpuscles may be reduced to ten per cent., or even less, of their original number. I have observed cases in which the number of corpuscles was as low as 500,000 or 600,000 per c.mm. instead of 5,000,000 as in health; the respirations never rising above twenty per minute, the breathing during quietude being perfectly tranquil throughout."

Of course, if one had abundant time in which to prepare, the best saline-alkaline fluid it would be one identical in its components and their proportionate quantities with those found in blood-serum. Most surgical text-books give a formula more or less approaching this, though simpler. Of late it has been recommended by Ludwig, of Leipsic, to add to our saline-alkaline water a little sugar; this being a natural ingredient of blood.

Simplest of all, and so far as we can see, practically about as good as the most complicated of the formulæ, is warm water plus a little table-salt. It has the great advantage, too, of being always easily obtainable when wanted. The best proportion of salt is six in one thousand parts, or about that of blood serum. This would be, roughly, a heaped teaspoonful to a quart of warm water. The water should first be boiled, for reasons of asepsis.

We must never forget the salt. Such an omission would be fatal. Pure water, devoid of sodium chloride, when injected in any considerable amount, will at once dissolve out of the blood cells their hæmoglobin and thus promptly kill the patient.

Now for the new and simple technique to which I alluded a few minutes ago.

It involves no cutting whatever, no searching for a collapsed vein, no freshened knowledge of anatomy, no tying in a cannula, no cannula at all, in fact. All the appliances needed are such as to be right at hand (it can reasonably be assumed) in nearly every instance. The solution has already been spoken of. The instruments are three: an ordinary Davidson's syringe; an ordinary soft rubber catheter, or a small rubber drainage-tube; an ordinary hypodermatic needle—large size preferred, though this is not essential.

Even if our patient is pulseless at the wrist we can almost to a certainty feel the femoral beating just below Poupart's ligament. Now take the needle—not as yet attached to the catheter—and push it directly into this artery, going slowly, until bright-red blood is seen to well up from within the needle. (As the artery here is large enough to carry a lead-pencil, the needle will not easily miss it, with a little care.)

As soon as the arterial blood is seen in the needle, slip over its base the catheter—already attached to the syringe, the nozzle of which has entered the catheter at the eye, and both being filled with the warm salt-water—and tie a thread tightly about the catheter, securing it to the base of the needle.

Now, holding the needle in place firmly and steadily, pump the fluid directly into the arterial current. To avoid possible pumping of air by an old or leaky syringe, make an abundance of the salt water, and keep the entire syringe, with the hand working it, beneath the surface.[1]

That is the whole story; and how very simple, how very easy! A Davidson syringe is to be had in almost every home. Every doctor carries, or should carry, if out of the city, a soft catheter and a hypodermatic syringe. From the moment the determination to use saline infusion is reached, until the moment that infusion is actually entering the blood-current need not average five minutes.

If men prefer a simple to a comparatively complicated thing, otherwise of equal merit, then will they. I must

[1] William Hunter: Third Lecture on Transfusion, delivered at the Royal College of Surgeons. British Medical Journal, p. 309, August 10, 1889.

[1] It is hardly necessary, perhaps, to remark that an assistant's fingers pinching the tube during emptying of the bulb will prevent regurgitation, if the valves leak.

believe, prefer this method to a cutting operation, with searching for a small and collapsed vein, tying-in of a cannula, etc.

Should it be objected that this plan injures a very important artery, I would reply, that this is decidedly a lesser evil of those which confront the patient dying from loss of circulating-fluid.[1] Furthermore, I have used this plan upon the human subject, saving the patient's life, as will presently be detailed to you, and with no subsequent annoyance whatever regarding the femoral artery.

A further advantage of this technique is the fact that thereby it is difficult to make the otherwise common error of throwing in the injection-fluid too fast, suddenly overwhelming the tired heart. Until one has tried it, one hardly realizes how much the intra-vascular pressure will obstruct the inward flow through the needle, even in a patient with a badly flagging heart. There will be so much resistance that it will seem as if the needle *must* be plugged with a clot or some other foreign body; so slowly, in spite of vigorous pumping, does the stream pass in. And yet in the course of a half-hour of steady work a pint or more can be made to enter.

Reflecting that occasionally the Davidson syringe may not be promptly obtainable, I have experimented with this plan upon the dog, using gravity as a force, by means of a fountain-syringe. If the reservoir be elevated about six feet, it will succeed perfectly well. If much lower than this, the intra-vascular pressure may still be enough, after even a severe bleeding, actually to force the arterial blood *up* the needle and into the tube, instead of the reverse!

Although during and after a considerable bleeding the arterial tone may be maintained by reflex action so as to equal or perhaps for a time exceed the normal blood-pressure, yet when the bleeding is carried to faintness the diminished cardiac vigor would result in lowered pressure. Such loss of blood as would require saline infusion would in all likelihood be accompanied by faintness; and consequently, if the method by gravity be used, the reservoir need hardly be higher than the altitude needed to overcome the average pressure in the unbled femoral, which is in man about one hundred and twenty millimetres of Hg. It is estimated that a pressure of 220 mm. of Hg. may *possibly* be found in the unbled human carotid. For the lower, or average, pressure just given, the equivalent in a capillary column of normal salt-solution (6 to 1,000) would be a height above the blood vessel of 1.626 m., or rather more than five feet; for the possible higher pressure named, 2.71 m.

Let me here remark that I am indebted to Professor John G. Curtis, of the College of Physicians and Surgeons of New York, for many courtesies; who also in the following experiments, as well as many others, in different lines, made during the past winter and spring, kindly put his physiological laboratory and its appliances at my service.

On May 15, 1891, I operated, Dr. F. J. Brockway assisting, on a dog weighing beforehand 10.4 kilos (22.73 pounds avoirdupois). Three hundred cubic centimetres of blood were taken from the right common carotid. Thereafter his pulse could only be felt in the femoral. Then, with an ordinary hypodermatic needle inserted into the femoral artery, we injected the same amount of warm, normal salt-solution, using the technique just described. Instead of a Davidson, a fountain-syringe was employed; the level of the fluid in the bag being five feet four and a half inches above the artery. It required fifteen minutes for the 300 c.c., to enter this dog's circulation.

If in dogs a rule which applies to humanity holds good, namely, that the quantity of blood equals about one-thirteenth of the bodily weight, then this dog had, before bleeding, about one and three-fourths pound of blood. As 300 c.c. (about ten ounces) were drawn, this would be proportionally equivalent to a loss (and subsequent replacement by other fluid) of nearly two quarts from a man weighing, before bleeding, one hundred and fifty pounds.

I have with me to-day, for your inspection, a very interesting kymographic tracing by the mercurial manometer, taken from another dog upon whom I made a similar experiment, but for a somewhat different purpose. This was to test the effect of *extremely hot* saline infusion, as distinguished from the same fluid used at the temperature of the body.

Whoever has seen cases of cardiac failure upon the operating-table, whether from anæsthetics or from other causes, knows that surgeons rely much for resuscitation upon the application of almost scalding hot wet cloths over the heart. As in many such instances the patient is devoid of reflexes, being completely anæsthetized, I must believe that the undoubted stimulating effect of these applications is in such instances due to the direct extension of the heat until felt by the cardiac ganglia.

Whoever has noted the vigor with which unstriped muscle everywhere reacts to the use of heat—for example, the much stronger and decidedly more permanent uterine contractions which result from hot post-partal injections, as opposed to cold ones—must believe it probable that such unstriped muscle, forming as it does a most important tunic of the blood-vessels, would be greatly aided by *hot* saline infusion in regaining its lost tone. Perhaps, too, the central sympathetic centres would feel and respond to this stimulus.

Now, since a more vigorous cardiac action, accompanied by a somewhat restored vascular tone, would go far toward recovery, both from hemorrhage and its attendant shock, I have felt that the experiment was well worth trying.

A priori, it would seem safe to employ this salt-water as hot as the hand can possibly bear (which is about 49° C., 120° F.), since globulin only coagulates at 70° C.[1] (158° F.), and serum-albumin at 72° C.[2] (162° F.), or about forty degrees F. hotter than the hand can support.

On May 15, 1891, I operated[3] on a large dog, weighing before bleeding, 16.77 kilos. On the 1 in 13 hypothesis his normal weight of blood would have been 1,290 grammes, or (allowing for specific gravity of blood) about 1,222.75 c.c. The cannula of the Hg. manometer was inserted into the right carotid. The right femoral was used for bleeding, the left femoral for injection of the hot salt-solution. Professor Curtis superintended the working of the kymographic needle. Dr. F. J. Brockway assisted me. We drew 563 c.c. of blood. This was a tremendous loss, nearly equal to one-half the total amount the dog possessed. Now, 250 c.c. of the normal salt-solution were slowly thrown in, at a temperature of 120° F. This was less than half the amount of blood lost, and yet the effect of its introduction upon the cardiac vigor, vascular contraction, or both, was striking in the extreme. As evidenced by this kymographic tracing, herewith presented to you, the pulse seemed almost as powerful for the time being as before a drop of blood had been lost.

Subsequently a further bleeding of 470 c.c. was permitted; now the loss being one of blood mingled with salt-solution, of course. In attempting to replace this

[1] In this connection it is worthy of note that a recent method of treating aneurism inoperable by pressure, ligation, or other usual plans, and advocated by Macewen, the Glasgow surgeon, is *needling*. Professor J. A. Wyeth, of this city, operated upon an aneurism of the arch of the aorta by this plan at the Polyclinic Hospital a year ago. He inserted into the diseased vessel thirteen needles, with one of which he lightly scratched the opposite wall of the sac. All were left in place twelve hours. Ten days later thirteen needles were again inserted, and left twelve hours. The same treatment was repeated a third time, after another ten-days' interval. Dr. Wyeth reports the result at the present date as favorable. The sac is distinctly smaller.

If a diseased arterial wall will safely bear such needling as this for twelve hours, and repeatedly, it would seem a fair inference that a sound artery may without serious hurt bear a single needle for a single half-hour.

[3] In both this and all experiments on animals I have used morphine enough to prevent suffering.

loss once more by hot saline injection, a mistake, a most interesting and instructive one, was made. Dr. Brockway and I each supposed that the other had added the salt to the hot water, for the fresh injection; whereas, in fact, neither had done so. And within a minute after receiving a considerable amount of this plain water injection, the animal died.

On May 17, 1891, I was given an opportunity to use in actual practice the points upon which I have dwelt in the last half of this paper. The patient, Mrs. L——, was a primipara, well formed, healthy, and with no previous indication of a tendency to the frightful flooding from which she suffered after delivery. Her physician is Dr. Howard Gillespie Myers.

He states that labor began at 9 P.M. on May 16th. The first stage was completed by midnight. Pains continued strong, and the baby was born at 2 A.M. Uterus contracted well, and in half an hour the placenta was expressed, by Credé's method, with ease. Bleeding was not unusual in amount thus far. A drachm of fluid extract of ergot was now given her. The doctor held the fundus uteri for some time. He remained at the patient's side, being anxious at the frequency of the pulse, which from the birth continued to be about one hundred. At 3.30 A.M. moderate hemorrhage began. Once more he took firm hold of the uterus, finding it doughy and soft. Manipulation led to contraction, with a gush of blood; followed by relaxation again. Ice over the fundus proved useless. Next, two or three quarts of hot-water douching, intra uterine, were employed; followed by contraction, but only a temporary one again, after which the steady outpour of blood went on. Dr. William D. Bell and Dr. George W. Leonard were called in. Several hypodermatic injections of ergot were made. An intra-uterine application of a cotton pledget soaked in vinegar was tried; result, same as before—a temporary contraction, then the continued free flow again. The foot of the bed was elevated, the extremities tightly bandaged to supply the brain and heart with more blood, and another hot intra-uterine douche was given, this time containing perchloride of iron. After this there was no further bleeding; Dr. Myers remarks that there could not well have been, as the patient seemed completely exsanguinated. For some time before I was sent for, and arrived, the patient had been unconscious, in muttering delirium, and the whole surface deathly cold.

When I saw her she looked moribund. Nothing at the first glance showed life save irregular gasping for breath, and the occasional delirious mutter. She was too weak to show restlessness. The skin was covered with cold sweat, the features pinched, the pupils dilated, the eyes looking glazed. Undoing the bandage on one extremity I found no pulse at the wrist, though the heart could faintly be heard beating very rapidly, and the finger just below Poupart's ligament could barely detect the artery. I do not think it likely that she could have lived an hour longer without saline infusion or else transfusion; and Dr. Myers shares this opinion.

As quickly as possible the normal salt-solution was prepared, *as hot as the hand could tolerate*. The hypodermatic needle was inserted in the right femoral artery, just below Poupart's ligament. Feeble as she was, a thread of arterial blood came slowly up the needle. The catheter was attached, and pumping by the Davidson syringe began. A full pint of the hot salt-water was thrown slowly into the artery, taking nearly half an hour. The proof that it did enter the current, and was not deposited in the connective tissue about the vessel, is the fact that no swelling was produced. A pint, or even a quarter-pint, of water injected into the connective-tissue spaces under the skin at any one place would produce a very prominent swelling.

During the operation the heat of the solution was maintained by keeping the vessel containing it in another of yet hotter water, to which boiling water was added as required.

Before this injection was half finished we were delighted to notice an evident improvement in the heart's action. By the end of the half-hour a faint pulse at the wrist was noticeable, and actually the delirium had ceased.

An interval of a half-hour was now allowed before further infusion, during which time she was kept well surrounded by hot applications (including a hot-water bag against the heart), received a hot beef-tea enema, and several small hypodermatic injections of strychnine sulphate and atropine sulphate, the former as a heart tonic, the latter as a respiratory and sympathetic stimulant. Also one small injection of equal parts of tincture of digitalis and tincture of strophanthus was used. Whiskey was freely introduced at many points by the needle.

At the end of this period she received a second full pint of the very hot normal salt solution. Differing from the first pint, this was thrown into the connective tissue of the thighs at some five or six different points. As fast as a moderately large swelling was produced, a fresh place was chosen, and one of the doctors briskly rubbed and diffused this tumor in a centripetal direction, and with vaselined hands. She was now conscious, and complained of the pain caused by these manipulations.

Briefly, from this point she began to rally more rapidly, and in a few hours was out of danger so far as her circulation was concerned. But for a number of days Dr. Myers hardly left her bedside, as her stomach needed the most assiduous care, almost everything being rejected. Rectal alimentation supported her during this period. When able to retain food *per os* once more, she made a speedy recovery. Her summer was spent in the Adirondacks, and to-day she is strong and well.

My reason, in this case, for varying the technique while injecting the second pint (by using the subcutaneous cellular tissue instead of the artery) was that I thought the circulation then sufficiently strong to absorb the solution into itself; and I did not wish to pierce the artery needlessly.

It would seem that if a patient requiring infusion were not in such extremely bad state as my case was at first, this latter method might do very well; but if a prompter and more certain effect be needed I should always prefer entering the artery with the needle.

At the time of operation upon this case I had never heard of saline infusion being employed by any other than the usual (that is, intravenous) method, with its cumbersome accompaniment of venesection, tying in of a cannula, etc. But shortly afterward I read in the *International Medical Annual* for 1891 a statement that subcutaneous injections of a normal salt-solution have been successfully used after post-partal hemorrhage in the Dresden Lying-in Hospital. The technique is not given either in the article or its bibliography.

Of course, *transfusion*—of whipped blood, into the subcutaneous tissues—has long been known. Casse, of Belgium, in 1879, experimented by this plan. As late as 1887, in Germany, H. von Ziemssen advocated it, using a large syringe and needle of abundant calibre, the patient being under chloroform meanwhile, and the blood being diffused by very vigorous rubbing.

As has been elsewhere remarked in this paper, *blood*-injection for hemorrhage, by this or any other plan, has now practically been dropped.

So far as the writer has been able to discover, the extremely simple and ready method of saline infusion herein described—that is, using an ordinary hypodermatic needle in an artery, etc.—has not heretofore been published; nor the suggestion of the value of a high temperature in the injected fluid, instead of that normal to the body.

Professor Helmholtz says that he has worked to gain knowledge for himself and not primarily to help science.

Opium Smoking is bringing ruin upon hundreds and thousands of families in India, according to a missionary who has been investigating the matter in Brazil.

THE TANNATE OF MERCURY IN THE TREATMENT OF SYPHILIS.[1]

By CHARLES W. ALLEN, M.D.,

MEMBER OF THE NEW YORK DERMATOLOGICAL SOCIETY; MEMBER OF THE AMERICAN DERMATOLOGICAL ASSOCIATION, ETC.

MR. PRESIDENT AND GENTLEMEN: We are inclined, I think, to look upon ourselves at the present day with no small amount of satisfaction, in the consciousness of having settled the question that mercury is the drug above all other drugs with which to combat and cure syphilis. After many years of, at times, hot and acrimonious controversy, all but a weak, though strong-headed, minority have been convinced that there is not, and some have gone so far as to believe that there cannot be, anything better. While believing most thoroughly in the value of mercury, a value scarcely equalled by any other drug in any other disease, it seems to me not beyond the possibilities, and I might even say probabilities, that the syphilographer of the future will look back and down upon us of to-day with much the same feelings which possess us when we think of our confrères of the sixteenth century, who puffed themselves up with pride in the discovery that nothing could compete with guiac as a specific for the pox. As the twenty-and-odd-century physician injects a little anti-syphilitic lymph beneath his patient's skin, he may feel for us as we now feel for those who have gone before. However, gentlemen, we are still in the nineteenth century and mercury is the best we have, and we must make the best of it. The only question which exercises us at the present time is in what manner to get the most benefit from its employment with the minimum of danger and discomfort. This is the question touched upon in the brief communication which I have the honor of bringing before you to-night, and one most worthy of our consideration. We know how powerful and dangerous a poison mercury is, still we are accustomed to deal with deadly drugs, and the knowledge that harm may come from their improper use does not detract in the slightest from our appreciation of their great value, or deter us in any way from employing them to accomplish our ends. It is probable that we do not yet know all there is to be known about the use of mercury, and it is certain that the drug is still much abused. I do not refer to the abuse heaped upon it by the non-believers, but the mal-use of the remedy which gives a certain warrant for their derogatory words. Compared with the days when it was believed that large doses should be given, and salivation was thought beneficial, the mercurial affections of to-day are mild and few, still accidental and unwelcome ptyalism is of altogether too frequent occurrence, and it too often happens that symptoms referable to an excess of mercury are mistaken for evidences of the original disease and the much-enduring patient is submitted to a further dosing.

Hydrargyrophobia is not an unusual affection among old syphilitics, and unfortunately is one which had some excuse for existing. A man who had been for a short time under my care recently shot himself, not, so far as I could learn, because he despaired of a cure of his disease, but because he conceived the idea that his troubles were the result of too much mercury. In this instance there was probably no foundation for his belief, although he had been treated by many different men, and had undoubtedly taken much medicine.

The practical question which first suggests itself to us in considering a new preparation is whether there is a demand or desire for it, whether those we already have at our command are not ample.

Syphilis cannot be regarded as an exception to the general rule in medicine, for so great is our desire for improved methods of treatment, so strong is our faith that the future holds better things in store, and so firm is our conviction that present means of cure are inadequate, that experimenters are constantly at work discovering new remedies, and despite the vast number which are being constantly brought forward, there are always to be found those who will give them fair clinical trial provided they have been properly placed before the profession.

It is due to this evident dissatisfaction with older methods, and the results obtainable with the old-time remedies, that many excellent substitutes for them have been discovered, and the spirit which prompts the clinical investigator to make trial of new remedies as they are introduced has saved many a valuable one to mankind which might otherwise have been lost. The disappointment which follows the trial of a hundred promising novelties does not weigh against the discovery that a single one is an improvement on those we have had before.

That a feeling exists that the mercurial preparations now most commonly employed are not wholly satisfactory is very evident from the fact that new ones are being constantly elaborated, and from the numerous attempts to devise a method of hypodermic medication which shall take the place of the older plans of treatment.

The inunction cure is highly esteemed by all who have had much experience with it. Mercury is in this way quickly introduced into the system. The dose is however uncertain, some skins absorb more rapidly than others and ptyalism is often produced quite precipitously. In those having delicate skin a dermatitis, folliculitis or even an eczema may be caused by the frictions. On account of its uncleanliness it is found impractical to employ it in certain cases. Decided objections are likewise to be made against the various forms of mercury given by the mouth. Of these calomel is especially prone to cause salivation in the adult and diarrhœa in children. It also often produces colicky cramps and various digestive derangements. Corrosive sublimate, which is much employed, is open to the same disadvantage and is capable of exciting severe gastro enteritis. The protiodide, which is probably the most largely employed form of mercury in this country, has, in addition to the above disadvantages, the further one that many object to the use of any iodine preparation in early syphilis and so reject the proto- as well as the bin-iodide. Some patients cannot take the protiodide at all, or only in such small dose that its use has to be abandoned. It often proves so irritating in the intestinal canal that constant watery diarrhœa follows its use. It is very unstable and prone to give up metallic mercury, or change into the biniodide. I mention these objections because it is with the protiodide especially that the tannate enters into competition.

The hypodermic injection of mercury has not become popular here, and I doubt if it ever will develop into a common method of treatment for Americans, but will rather be reserved for certain special cases. The stomach then remains the organ through which mercury must, in the main, be introduced into the system.

I think the objections given above to the more commonly employed mercurials are sufficient to warrant a search for something better.

Dr. Lustgarten, whom we have the honor of having with us to-night, was rewarded in such a search by discovering the hydrargyrum oxydulatum tannicum, or tannate of mercury, while working in the laboratory of Professor Ludwig in Vienna. The first published account of this preparation is found under the title "Ein Neues Quecksilberpräparat" in the *Wiener Medizinische Wochenschrift*, Nos. 11–14, 1884. Here the author describes the tannate as a dark yellowish-green powder, without taste or smell, which is not soluble so long as it is not decomposed. This is only slowly attacked by hot hydrochloric acid, but is quickly destroyed and decomposed by nitric, the fluid turning brown. If we pour upon a specimen of the powder even a very weak caustic or carbonate alkali a mouse-gray muddy deposit forms.

[1] Read before the New York Academy of Medicine, December 10, 1891.

Seen under the microscope this is found to be made up of exceedingly small granules, which in part are seen to be in active vibratory motion (*molekular bewegung*), which cease on the addition of an alcoholic solution of iodine, forming characteristic red and yellow crystals of iodide of mercury. If this deposit is washed by decantation it will amalgamate a shining piece of gold, showing it to be metallic mercury, of which numerous analyses have demonstrated the tannate to contain about fifty per cent.

The simplest mode of preparation, according to Leblond, consists in precipitating a solution of nitrate of mercury by a solution of tannate of soda in slight excess. A yellow precipitate is thrown down which rapidly changes to a greenish hue. This is the tannate of mercury. I pass for inspection a specimen of Merck's in crystal form and another of the powdered drug. The precipitate is washed by decantation until the decanted water no longer shows any precipitate by the acetate of lead, and no longer changes blue litmus paper. The precipitate is then filtered and allowed to dry in the open air.

Lustgarten found in seven cases evidences of mercury in the urine twenty-four hours after the tannate was administered, and Borowski found it excreted on the second day of treatment.

Petrini has shown by analysis of the saliva that at certain times the elimination by the buccal mucous membrane is more active than by the kidneys, and the elimination through the mouth is greater the longer the patient has been under treatment by the tannate, and the quantity as compared with that escaping in the urine is also greater.

To secure the secretions pilocarpine was injected hypodermically, and although the salivary flow was rendered very abundant, scarcely any perspiration took place. What little product of the sweat-glands was secured failed to show any mercury by chemical analysis. Up to the time of the introduction of the tannate only inorganic preparations, the iodides and chlorides, and metallic mercury had been known for internal use. The discovery of the tannate opened up a new field for the development of organic compounds, and following its introduction came in quick succession the formamide, asparagine, carbolic, salicylic, thymolic, benzoic, and other acids, which have become more or less favorably received, especially for hypodermic use.

About five years ago a representative of a leading pharmaceutical firm brought me a sample of tannate of mercury pills, and asked me to give them a trial in the hospital. They had not yet put them on their list and wanted the results of clinical experience before presenting them to the profession. Up to this time I had made no trial of the new preparation, but promised to do so, and report my results. I was furnished from time to time with a liberal supply of the one-grain pills, and after observing their effects for some time on a number of patients I made a verbal report of my favorable impression. The reports of others who had tried the remedy in the same way being also favorable, the firm began manufacturing the pills.

My experience with the tannate has been rather limited, extending to probably less that fifty cases, of which records of only thirty-five are available, and I do not propose to weary you by relating even these.

However, I think I have had sufficient opportunity to watch the effect of the drug to enable me to draw certain conclusions as to its value, and these I will give as briefly as possible. I have come to regard the tannate as an exceedingly efficacious preparation, showing its beneficial action on syphilitic products often in a remarkably prompt manner.

As a rule it does not disagree in any way with the patient, and is free from injurious effects upon the stomach and the processes of digestion. It does not affect the salivary secretion more than the protiodide.

In some cases, however, it is quite capable of causing stomatitis, even in doses which have been considered free from this danger. In several cases slight stomatitis has come on after a daily dose ranging from three to six grains, and the dose has had to be decreased in a number of instances where not over three or four grains were being taken daily.

I wish to emphasize this feature of treatment by the tannate because my experience differs from that of others and from the early observations of Dr. Lustgarten. Thirty centigrammes, or five grains, daily produced no such effect in his reported cases. I will say, however, that, so far as I can judge, the tannate is not more apt to cause salivation in dose of four grains daily than is the protiodide in dose of one grain, and when we consider that the tannate contains fifty per cent. of mercury and the protiodide over sixty-one per cent., the difference in effect is quite marked. I have had two instances of severe ptyalism, for which, however, the tannate should not be wholly blamed.

Miss H——, aged nineteen, came to my office the latter part of November, 1889. She presented a chancre of the lower lip which had existed for two weeks. On December 3d there occurred an extensive macular eruption, preceded by several days of fever, swelling of the knees, pains in the legs, and severe headache. The glands beneath the jaw on the right side were enormously enlarged. Up to this time there had been none but local treatment. I now prescribed one grain tannate of mercury pills and instructed the patient to take one three times daily for three days, then two pills at each dose for three days, and then one pill again at a dose until the next visit. On December 18th the patient returned suffering from ptyalism, and on inquiry I learned that she had mistaken my instructions and taken three pills thrice daily for the first three days, making twenty-seven grains, then two at a dose for an equal period, and three grains daily for the balance of the time, making an aggregate of about seventy grains in the fortnight. Her syphilis had been decidedly improved. The chancre had almost disappeared, the masses of glands had melted down considerably, and the eruption was fading rapidly, and by the 24th had almost entirely gone, and by this time the chancre was also well. There was no question as to the marked effect of the drug upon the lesions for they had all been especially severe. The pills were stopped at once and treatment directed to the salivation, which proved very annoying and did not get well for over two weeks. The bowels had not been at all affected, in spite of the decided effect upon the mucous membrane of the mouth.

The second instance occurred in a man who had been for some time rubbing blue ointment into the palms and soles. One-grain pills were begun on June 13th, and on the 19th, after taking only eighteen grains, salivation was noted. Here I attributed the effect on the glands of the mouth to the local inunctions quite as much as to the tannate.

I have given the tannate in several instances in daily dose of six grains for a considerable time without bad effect and have doubled this dose, giving four grains three times daily for a day or two with impunity, but I would not advise these larger doses, unless the increase has been gradual and carefully watched. In eight instances I have increased the dose as much as possible on account of disfiguring eruptions on the face in women, a class of cases in which a speedy removal of the lesions is always desirable. In two cases the tannate was combined with local treatment by means of emplastrum hydrargyri, an expedient always useful and often necessary before the infiltrations will give way. In a number of cases diarrhœa has been produced even in dose of three grains daily. I have a patient now under treatment who can take half a grain for months at a time, while one-grain doses give him looseness of the bowels and abdominal cramps. This patient has had no symptoms since the early secondary

stage, so that the larger doses have not been considered necessary.

As to the mode of administration, the tannate may be given in its pure state as a powder alone, mixed with sugar, licorice powder, and sugar of milk, or, as I have occasionally done where diarrhœa has come on, combined it with a few grains of tannin. Dispensary and hospital patients take the powder on the tongue without objection. For children it can be given in milk. My first and most extended experience has been with the gelatine-coated pill, but as these have till recently only been obtainable in size of one grain I have been having them made extemporaneously with extract and powder of licorice. Kaposi, in his recent work on syphilis, says that the tannate has been used in his clinic by the hypodermic method. A Pravez syringeful of the following, injected six or eight times, constitutes a cure :

℞. Hydrarg. oxyd. tannic..... 20 parts
Paraffin liq., or,
Olei vaselini..... 10 parts

It is said that this causes scarcely any pain, and is not followed by abscess. I have had no experience with this manner of using the tannate. By the mouth it is best given an hour after meals. An excess of greens, salads, and fruits should be excluded from the diet if there is much tendency to diarrhœa and cramps. As it has been pointed out that even weak alkaline solutions decompose the tannate, mineral waters should not be taken near the time for giving the drug.

As to the dose, I am more in favor of the half-grain than the grain for continuous employment three or four times a day. These half-grain doses can be multiplied as symptoms require it up to the point of toleration as indicated by tenderness of gums, or more rarely diarrhœa. As the symptoms disappear I usually decrease the dose to the half-grain standard, and keep the patient at that for months continuously, or with occasional short breaks. Sometimes this dose seems sufficient. A case of chancre of the tonsil with marked secondary manifestations in a young married woman was very well controlled without increasing this dose.

Dr. Lustgarten has pointed out the possible danger of giving the iodide of potassium at the same time with the tannate. In several instances I have given patients both drugs, with an interval between the doses, without producing any unpleasant effects. In one case, however, an obstinate diarrhœa did follow, but I could not attribute it to the combination, for at other times the tannate alone produced the same effect, and once the potash had to be stopped and the tannate continued, not on account of diarrhœa, but an iodide acne. This was a case of destructive gumma of the nose, in which local means were also added to save the organ. The tannate and iodide seemed to act well together here, but I cannot recommend it as free from danger.

I have tested the solubility of a variety of pills and tablet triturates which I have had in my office for a year or more. With one exception (a compressed "friable" pill, which was so hard that long soaking in water and considerable force were necessary for its disintegration) they broke down readily and the mass examined under the microscope showed the minute globular bodies in molecular motion described by Dr. Lustgarten. I have also examined different samples of Merck's tannate in the granular and powdered state, and found it always to act the same under reagents and appear about the same under the microscope. I mention this because Dr. Keyes says, in the last edition of his book, that the different preparations vary greatly in their effects in his hands.

Undoubtedly the drug employed should be procured from some reputable firm. It is not claimed for the tannate in any way that it will shorten the time of treatment, or that it has a power over other preparations of preventing relapses. I do not expect the tannate to wholly take the place of any other preparation of mercury. I do not use it to the exclusion of several other forms of mercury. I believe in inunctions, and usually begin treatment with a course of rubbings. I also favor a mild continuous course of hydrarg. cum cret. in certain cases, but I do prefer the tannate to the protiodide so far as my experience with it goes.

The advantages which it seems to me the tannate possesses over other preparations of mercury given by way of the stomach are : 1. That it is stable, does not decompose, dissolve, or change readily. 2. It is quickly assimilated and quickly eliminated. 3. A relatively large quantity of mercury can be thus given with safety, and a relatively large proportion is absorbed, as shown by quantitative analysis of the urine. 4. It is not so prone in my experience to cause salivation as calomel and the protiodide. 5. It is not so likely to cause diarrhœa and gastro-enteritis as the bichloride and protiodide. 6. It is well tolerated by children in dose of 0.02 to 0.04 per day (gr. $\frac{1}{3}$ to $\frac{2}{3}$). Monti speaks well of it and finds it does not affect the digestive organs. 7. Being unchanged in the stomach and only decomposed after it enters the alkaline contents of the small intestine the stomach escapes any possible irritation, and as we calculate to introduce something like two ounces of mercury by this organ during an antisyphilitic course, it becomes very necessary to give it in such a way as not to upset the stomach, and hence our calculations.

LITERATURE.

The literature of the subject is rather sparse, especially in this country. Writings which I have found are :

Lustgarten : Wiener Medicinische Wochenschrift, Nos. 11–14, 1884.
Pauly : Berliner Klinische Wochenschrift, No. 47, 1884.
Borowski : Russkaja Medicina.

Balzer, Finger, Kaposi, Keyes, Lang, Lesser, Neisser, Taylor, in recent handbooks, etc.

696 MADISON AVENUE.

Queer Things in Literature Concerning Doctors and their Doings.—In the *Revue des Deux Mondes*, June 15, 1877, according to a French journal, the following radical operation for croup is mentioned in the "Mari de Suzanne :" "She told me in a few broken words that Pierre had an inflammatory throat trouble after my departure. . . . Félicien cared for him from the first. . . . Incision of the artery (*sic*) became necessary, followed by a fatal issue, the instant the lips were applied. I listened speechless, paralyzed by emotion." No wonder! The *Mercredi médical*, October 28, 1891, quotes from a French novel, which treats of one Dr. Livournet, who "pulls Xavier through an attack of croupous scarlatina, and then cures Gilberte of abominable meningitis." Later, in the same book, is noted a remarkable phenomenon : "At the bottom of this glass the chloroform had left its opium-tinctured and unsavory deposit." Sometimes botany, as well as materia medica, is astray in secular literature. Mendes, in "Zo'har," speaks of the aconite plant, with its blossoms like white umbrellas. "Umbrellas!" Never. And aconite is white so seldom. Why not say in blue clusters? It is almost as poetical, and much more truthful.

Urticaria of the Throat.—Dr. Laveran reports the case of a patient of thirty years who had each morning crops of urticarial wheals on the hands, feet, and shoulders, and finally presented a crop localized in the throat, with œdema of the uvula and pillars of the tonsils, attended with dysphagia and dyspnœa. A similar condition was seen by Dr. Sevestre in a mother and son after the ingestion of mussels.—*Journal de Médecine*, No. 20, 1891.

MEDICAL LEGISLATION IN 1891.

By HENRY A RILEY A.B, LL.B,
NEW YORK.

Alabama, Arizona, Arkansas, California, and Colorado.—There appear from time to time in the medical journals articles giving summaries of special laws enacted by the various State Legislatures, but the great body of legislation interesting to the profession is not often gathered together so that an intelligent opinion can be formed of the influences at work in the different States to elevate medical practice and instruction and to guard the public health.

It seems, therefore, likely that a general statement of the legislation actually placed on the statute-book in 1891 will be of interest. Some of the States have not yet published the laws recently passed, and consequently the summary will not be absolutely complete, but in the case of the great majority of the States holding sessions of the Legislature the laws are now accessible and can be presented.

It may be said in a general way that the past year has been a period of great activity in medical legislation, and many of the States have been endeavoring to secure a higher grade of medical instruction and to place greater safeguards about the admission to practice. There have also been in several of the States laws passed regulating the practice of pharmacy and dentistry. In collateral matters affecting the care for the insane and criminals, and the preservation of public health, there has been quite a body of new legislation.

In considering the subject it will be well to take up the different States in their alphabetical order.

In Alabama there was no legislation in regard to the practice of medicine, but there were some laws passed of interest concerning medical instruction. An appropriation of $10,000 was made for the Mobile Medical College, which is a department of the State University, to obtain new appliances, apparatus, and a laboratory, and to compensate the faculty for services rendered in teaching non paying students. The act states that it is to secure these objects and "to maintain said college and its facilities on a par with the most advanced colleges of the country."

It was also enacted that physiology and hygiene were to be taught in the public schools as regularly as other branches, and with especial reference to the nature of alcoholic drinks and narcotics and their effect upon the human system. No teacher was to receive a certificate in the future who had not passed an examination in these branches.

The convict lease system in the South is generally felt to be a disgrace to civilization, and many efforts have been made to improve it or to abolish it altogether. It is of interest, therefore, to note that Alabama has appointed a commission to consider the means of improving the penitentiary and convict systems of the State and to prepare a bill providing for a new and complete convict system.

It was declared to be a misdemeanor for anyone to sell or give to any minor under eighteen years of age any cigarettes, cigarette tobacco, or cigarette paper, and the penalty was fixed at a fine not less than $10 and not exceeding $50, or imprisonment not to exceed thirty days.

A Quarantine Board of Mobile Bay was established, and an appropriation made for erecting a suitable quarantine plant with the most modern appliances for disinfecting and fumigating.

The Alabama Insane Hospital was authorized to spend $12,500 for farm lands and to erect buildings for the accommodation of persons who might be benefited by out-door work.

The Alabama School for Negro Deaf-Mutes and Blind was established at Talladega, and $12,000 appropriated for the erection of buildings.

There were numerous bills passed prohibiting the sale or giving away of liquor within distances varying from one-half a mile to five miles from specified school-houses or churches, but no exemption was allowed, as is the case in some other States, for prescriptions by physicians.

In Arizona the Territorial Legislature provided that the University of Arizona should have a Department for the Education of the Deaf, Dumb, and Blind, and directed the Board of Regents to make suitable provisions for their instruction according to the most improved and modern methods. It would seem, however, that the demand for such a department was not very pressing, as it was ordered that the law was not to go into effect until at least five residents of the Territory had made application for education.

A general law was passed providing for county hospitals, but this was to be done under a contract system. The care of the indigent sick, including medical attendance and medicines, was placed in the hands of the County Boards of Supervisors, who were to advertise for bids. Each bid must specify distinctly the amount to be charged for each day's attendance upon the indigent sick, including medical aid, food, lodging, and clothing, and the successful bidder was to give a bond of $5,000.

Persons afflicted with cholera, yellow fever, or smallpox were not to be allowed in the county hospitals, but the Boards of Supervisors were authorized to make temporary regulations for the care of such cases.

It was declared to be a misdemeanor for anyone to sell, give, or furnish any cigarettes to minors under sixteen years of age, and the punishment was fixed at a fine of not less than $10 and not more than $100.

In Arkansas the condition of medical ethics may be imagined when it is found that the Legislature ordained that physicians employing "cappers" or "steerers" should have their licenses revoked. It is understood that the disgraceful competition between physicians at the Hot Springs for new arrivals was the reasou for the passage of this law. The act mentioned eight instances of unprofessional conduct which would warrant the revocation of the license. They are as follows:

1. Procuring or aiding and abetting in the procuring of criminal abortion.
2. Employing or using what are known as cappers, steerers, or drummers, or the subsidizing of hotels or boarding-houses to procure practice.
3. The obtaining of a fee on the assurance that a manifestly incurable disease can be permanently cured.
4. The wilful betrayal of a professional secret to the detriment of a patron.
5. All advertisements of medical business in which untruthful and improbable statements are made.
6. All advertisements of any medicine or means whereby the monthly periods of women can be regulated or the menses re-established.
7. Conviction of any offence involving moral turpitude.
8. Habitual drunkenness.

If a license is revoked for any one of the preceding grounds the offender may apply for a new license after the expiration of a year, and it may be granted by the Board of Medical Examiners if satisfied of the reformation of the applicant.

A State Board of Pharmacy was established, consisting of five pharmacists who had been engaged in active business for at least five years. Two meetings a year must be held for the purpose of examining applicants, and in the meantime any member of the Board could, at his discretion, issue a temporary license, good until the succeeding meeting.

The Board was directed to register and issue licenses to all persons engaged in the business of pharmacy at the time of the passage of the act.

All graduates of schools or colleges requiring three years' experience before granting diplomas are entitled to be registered without examination.

All other persons desiring to become pharmacists must

be examined, and if the examination is satisfactory to a majority of the Board the certificate must be issued.

If a person not a registered pharmacist conducts a pharmacy, it is a misdemeanor and is punished by a fine not exceeding $100.

The law does not apply to physicians putting up their own prescriptions, nor to articles commonly known as "grocers' drugs," nor to patent medicines. A conviction for the illegal sale of intoxicating liquor and a cessation of business for twelve months will cause the license to be revoked.

There are numerous laws prohibiting the selling or giving away of intoxicating liquor within distances from individual school-houses or churches varying from three to five miles, but they all seem to permit physicians to prescribe alcohol or whiskey in strict administration of medicine. Some of the laws forbid such prescriptions unless the physician shall have previously filed with the clerk of the Circuit Court an affidavit substantially like the following: "I, ——, do solemnly swear or affirm that I am a regular practising physician, duly qualified as such under the laws of Arkansas, and that I will not prescribe, sell, or give away, or cause to be given away, any vinous, ardent, malt, fermented, or intoxicating liquor, or any compound or preparation thereof commonly called tonics or bitters, medicated liquors, or by whatsoever name the same maybe called or known, unless it be for actual medical purposes, and not then unless I believe the quantity given or prescribed will be necessary in the proper treatment of the disease from which the patient under my charge is at the time suffering."

The fines for violations of these laws range from $25 to $500.

To engage in a prize-fight with or without gloves, or to act as second or referee, is made a felony, with imprisonment in the State Prison for not less than one year and not more than three.

The Insane Asylum was ordered to be enlarged to accommodate three hundred additional patients, and $85,000 was appropriated for this purpose.

In California an elaborate law was passed regulating the practice of pharmacy and the sale of poisons. After January 1, 1892, it was declared to be unlawful for anyone to conduct a pharmacy or compound prescriptions who was not a registered pharmacist. A registered pharmacist must be either a graduate of pharmacy, a licentiate, or a practising pharmacist.

Graduates must have had four years' experience and have a diploma from a legally constituted college of pharmacy. Licentiates must have had four years' experience and have passed an examination before the State Board of Pharmacy or present satisfactory credentials to the Board. Practising pharmacists are those who are conducting pharmacies at the time of the passage of the act. Every person coming under the last class must present satisfactory proof to the Board before January 1, 1892, that he was engaged in the preparation and compounding of drugs at the time the act was passed.

Within thirty days from date of enactment the Governor was to appoint seven competent pharmacists to constitute the State Board of Pharmacy, and the term of office was to be four years.

The fee for an examination was fixed at $5. The vexed question of the ownership of the prescription is disposed of, but not settled, by the direction that every registered pharmacist should file or caused to be filed all physicians' prescriptions compounded or dispensed in his pharmacy or store. They shall be preserved for two years, and the pharmacist shall furnish a correct copy of any prescription upon the order or request of the attending physician.

The Board, when written complaint is made, is directed to make a thorough investigation into the quality of drugs, chemicals, or medicines, and if the facts justify, to notify the District Attorney of the results.

The act specifies that certain poisons mentioned in schedules A and B shall not be sold without being labelled "Poisons." the name of the article given and that of the seller, and not at all unless the buyer knows their poisonous quality and intends to use them legitimately. In the case of schedule A the pharmacist must keep a register giving date of sale, name and address of purchaser, the purpose, and name of dispenser, and this register shall be open to inspection by the proper authorities and be kept for five years. The schedules are as follows:

Schedule A.—Arsenic, corrosive sublimate, cyanide of potassium, hydrocyanic acid, strychnia, cocaine, and all other poisonous vegetable alkaloids and their salts, opium and all its preparations, except those which contain less than two grains to the ounce.

Schedule B.—Aconite, belladonna, colchicum, conium, nux vomica, savin, cantharides, phosphorus, digitalis, and their pharmaceutical preparations, croton oil, chloroform, chloral, sulphate of zinc, sugar of lead, mineral acids, carbolic acid, oxalic acid, white precipitate, red precipitate, biniodide of mercury, essential oil of almonds.

These sections in regard to poisons do not apply to physicians' prescriptions, nor if the bottle or package contains no more than one dose.

The procuring a false register as a pharmacist is made a misdemeanor, and the penalty a fine not to exceed $200.

The act does not apply to the business of practising physicians who do not keep an open store, nor to an exclusively wholesale business, except those portions relating to the labelling of poisons, nor to proprietary medicines in the original packages. California also forbids the sale or gift of tobacco or its preparations to anyone who is in fact under the age of sixteen, but makes the curious provision that the law is not deemed to apply to an article furnished on a prescription from a physician authorized by law to practise medicine, nor to persons who supply such articles to their children, nor to sales made to minors upon the written consent of the parents or guardians of such minors.

With these exceptions the sale or gift of tobacco is made a misdemeanor and punished by a fine not exceeding $100.

When twenty-five or more persons petition the Board of Supervisors for the formation of a sanitary district, specifying the bounds of the desired district, there must be an election held within thirty days to decide whether the majority of voters desire to have such sanitary district created. If they do, a Board is created which has the power to construct and maintain sewers, to remove garbage, to guard against the spread of contagious or infectious diseases, and to provide for the isolation of persons and houses afflicted with such diseases. The Board has power to enforce its regulations by fine and imprisonment.

A law directs the execution of persons condemned to death within a period from sixty six to ninety days after the sentence. If the Warden of the State Prison believes a condemned murderer to be insane he can, with the concurrence of the Judge of the Superior Court, summon twelve persons to inquire into the matter. If decided to be sane the Warden must execute the judgment, if insane he must suspend execution until he receives a warrant from the Governor or the Judge of the Superior Court directing execution.

If the convicted murderer is a woman supposed to be pregnant the Warden may summon a jury of three physicians, and the result of the inquisition, if she is found to be pregnant, must be forwarded to the Governor and the execution suspended. When satisfied that the woman is no longer pregnant the Governor may appoint a day for the execution.

A general act provides for a uniform system of county and township government, and authorizes the coroner to hold inquests. He is authorized to subpœna a physician or surgeon to inspect the body, or a chemist to make an analysis or hold a post mortem examination

of the deceased and give a professional opinion as to the cause of death.

An appropriation of $5,000 is made to send experts to Australia, New Zealand, and other countries to collect and import parasites and predaceous insects for distribution under the supervision of the State Board of Horticulture.

In the Southern California State Asylum for the Insane and Inebriates, the latter may be admitted on the order of a Judge of the Superior Court after investigation by two physicians and other credible witnesses. The commitment cannot be for a longer period than one year, and if not cured within that time the patient must be discharged as a confirmed inebriate. An appropriation of $125,000 is made for additional buildings for the California Home for the Care and Training of Feeble-Minded Children at Glen Ellen, and one of $55,000 for furnishing, etc., at the Southern California State Hospital for the Insane.

In Colorado it is declared unlawful for anyone to practise dentistry or to receive a license from the Board of Dental Examiners unless, in addition to other qualifications presented by the Board, he shall have graduated or received a diploma from a reputable chartered institution where dentistry is taught, or have received a license from the Board of another State.

The act does not apply to certificates to practise dentistry previously, and does not prevent authorized physicians or surgeons from extracting teeth.

Any person administering poison or using instruments with the intention of procuring a miscarriage shall be imprisoned for a period not to exceed three years, and fined in a sum not exceeding $1,000. If the woman dies the person is guilty of murder, unless it appears that the miscarriage was caused by the advice of physicians and with the intent of saving the life of the woman.

Every male person of fourteen years and upward who has carnal knowledge of a female under sixteen years of age, with or without her consent, is guilty of rape, and may be imprisoned for a period not less than one year and not over twenty.

It is also declared to be unlawful for anyone to sell or give cigarettes to any minor under sixteen years of age. The penalty for the first offence is a fine not exceeding $100, or imprisonment not exceeding three months, or both. For subsequent offences the fine may be $200, and the term of imprisonment six months.

A State Board of Charities and Correction consisting of six persons was established. It was given power to investigate the whole system of public charities and correctional institutions, to examine into the condition and management of all prisons, jails, reformatories, reform and industrial schools, hospitals, infirmaries, orphanages, public and private retreats and asylums for the insane, and any and all other institutions receiving aid from the State. All plans for jails, hospitals, and similar buildings shall be submitted to the Board for suggestions, criticisms, and approval before the same shall be adopted by the State, county, or municipal authorities.

An investigation may be made into the condition of any institution, and the Board must make biennial reports to the Governor.

An appropriation of $30,000 is made for a dormitory for girls at the Institution for Education of the Deaf and Blind, and one of $60,000 for the removal of old buildings and the erection and furnishing of a new one for female patients at the State Insane Asylum.

The salary of the State Veterinary Surgeon is placed at $1,500, and he is obliged to give a bond for $10,000 to secure the proper performance of his duties.

The Connecticut and Florida statutes have not been published.

(To be continued.)

Koch is Still Working on Tuberculin, and hopes to make it gradually less and less deadly.

ATROPINE IN HÆMOPTYSIS.[1]

By N. W. SOBLE, M.D.,

ROCHESTER, N. Y.

It is not the object of this paper to discuss nor to name the various remedies that have been used in the treatment of hemorrhage from the blood-vessels of the lungs. To a great extent the use of the remedies has been empirical and not based upon a sound scientific foundation.

Before mentioning the drug to which I would invite your attention, it is necessary to review for a moment one or two anatomical and physiological facts in connection with the blood-vessels of the lungs.

The anatomical structure of the blood-vessels does not differ materially from the structure of the blood vessels of the body in general, excepting that the walls of the capillaries of the lungs are exceedingly thin. We find, however, a marked difference in the nerve-supply of the pulmonary blood-vessels, principally in the vaso-motor system. It is a fact well known to physiologists that the blood-vessels or arteries of the lungs have practically no vaso-motor nerves. No experimenter has ever been able to positively demonstrate the presence of such nerves. It is also quite well established that the tonus of the pulmonary arteries is very slight, and that the pressure in these vessels is very little influenced by nervous stimulation or by changes in the action of the heart, such as affect the systemic circulation.

Sir James Andrew in the last Harveian oration said: "The pulmonary and systemic circulations are in reality independent to a great extent; we cannot judge of the state of pulmonary circulation by the pulse at the wrist, as is often attempted. The pulmonary circulation is under decidedly lesser vaso-motor control than the systemic circulation."

Sir James gives a long alphabetical list of drugs that have been recommended in hæmoptysis, and closes by saying that in looking through the list it gives a very good illustration of the old axiom that when many drugs are supposed to cure one and the same disease we may safely hold that few, if any, of them have the least influence over it.

The remedy which I would beg leave to indorse, in the treatment of pulmonary hemorrhage in all grades of severity, is atropine sulphate, administered hypodermatically. In studying the physiological effects of atropine, Professor Roberts Bartholow says: "After the injection of an ordinary dose of atropine a decided slowing of the heart takes place. But there is first a decided increase in the number of the pulse beats. This action has been shown to be produced by, firstly, a stimulation of the cardiac ganglia, and, secondly, by a paralyzing action on the pneumogastric terminal filaments. In other words, the motor power of the heart is increased, while the inhibitory power is diminished. The effect of atropine on the vaso-motor centres is not confined to the cardiac ganglia, but extends to the vaso-motor ganglia throughout the body."

Bartholow further says: "It is a singular fact that the influence of atropine rapidly produces a state of over-excitation, and the irritability of the vaso-motor system, at first increased, soon diminishes, the heart action becomes weaker, the blood-vessels dilate, and blood pressure sinks below the normal." Upon this physiological fact is based the good results observed and obtained by the use of atropine hypodermatically in the treatment of pulmonary hemorrhage. It acts on exactly the same principle as does ligating the extremities in the same condition, and is a measure which no one should fail to employ in every severe case of bleeding from the lungs.

Dr. Cardarrilli, an Italian physiologist of repute, after making experiments in sixty-five cases of functional cardiac diseases, comes to the conclusion that arterial press-

[1] Read before the Medical Association of Central New York, June 2, 1891.

ure is reduced by the hypodermatic administration of atropine in doses varying from $\frac{1}{150}$ to $\frac{1}{32}$ grain.

Atropine must be given in large doses in order quickly to overcome the primary effect it possesses of increasing arterial pressure. If the dose be sufficient this primary effect is almost nil.

Professor Brunton, in speaking of the effects of atropine upon blood pressure, says: "Atropine has a powerful action, but this differs completely with the size of the dose. Small doses cause temporary contraction of vessels, which soon passes off and the vessels return to their normal condition. Medium doses cause primary contraction, which soon passes off, and instead of returning to the normal condition, passes into dilatation and then returns to the normal. Large or full physiological doses possess a similar effect, but instead of the dilatation passing away and the vessels returning to their normal condition the dilatation persists." In speaking of the effect this drug has over the vaso-motor centres, the same author says: "That while atropine in small doses stimulates the vaso motor centres, large doses depress or paralyze them."

Upon this principle—that of reducing blood pressure—is based the ancient and now justly discarded method of treating pulmonary hemorrhage by venesection. Emetics have been recommended having the same end in view; objection to this is obvious.

Ringer, in his "Hand-book of Therapeutics," quoting Dr. John Harley, says: "The first effect of belladonna on the pulse is to increase its quickness, fulness, and force. Small doses at the same time increase blood pressure. This continues to a certain extent, after which the pulse diminishes in frequency and loses in strength, and this is produced mainly by vaso-dilatation."

On page 522 of Ringer's "Hand-book" Dr. Harley is made to say, distinctly: "Moderate doses of atropine contract the arteries, while larger doses dilate them, the dilatation being due to exhaustion of the sympathetic system resulting from previous over-stimulation.

As far as my researches on this point permit me to speak, Professor Lebert, of Breslau, was the first to use atropine hypodermatically for the arrest of hemorrhage from the lungs, and this as far back as 1868, but the treatment was not generally adopted until quite recently. At the present time periodical medical literature abounds in reports of cases treated by this drug, and satisfactory results are frequently reported.

An editorial in a recent number of the MEDICAL RECORD says, under the heading "A Novel Treatment of Pulmonary Hemorrhage": "At a meeting of the Victoria Medical Society, Dr. R. A. Sterling reported a case of profuse bleeding from the lungs in which all remedies had failed to check the bleeding, which was sufficiently severe to threaten immediate death, but in which the hypodermatic injection of $\frac{1}{150}$ grain of atropine immediately controlled the hemorrhage. Thinking the cessation accidental the doctor omitted the treatment for twelve hours, with the result of a fresh and severe attack of bleeding, which was at once controlled by a renewal of the treatment mentioned above"

I have employed this treatment in four cases. In all of these cases there was little doubt that the bleeding came from the blood-vessels of the lungs. In most of them, particularly the earlier ones, other remedies had been tried in vain.

In regard to the size of the dose used, no definite rule was allowed to guide the administration, but the state of the pupils was watched, and enough atropine given to rapidly dilate them. That is the only safe guide to the certain effect of this drug in this condition. When troublesome cough was present, small doses of morphine were combined with the atropine, and this did not seem to lessen the effect. The limbs were usually ligated, small pieces of ice given to swallow, and the patient kept absolutely quiet.

The following is the history of a case that is a fair example of all I have treated:

M. B——, aged thirty-four, by occupation a salesman; gave a tubercular family history on the maternal side; resembles his mother; denied rheumatic, malarial, venereal, and alcoholic histories; has always been in good health. Without any extraordinary amount of physical exertion he was, on February 19, 1890, taken with a sudden and profuse flow of blood from the mouth and nose, and when seen had lost a great deal of blood, was pale, and in a greatly exhausted state.

The patient was in bed, and his clothes, bedclothes, and the carpet were saturated with blood; by his side stood a wash-basin more than half filled with bright arterial blood. Whenever the man moved or coughed he brought up more blood. After a brief examination I felt satisfied that the blood came from the lungs, and treatment was commenced accordingly. The patient was first rapidly cleaned up, calmed, and the room was cleared of numberless sympathetic neighbors. Ice was applied to the chest and small pieces given to swallow. At this time I had not yet used atropine for this condition, but proceeded to treat my patient with the following remedies: Normal liquid ergot was first injected hypodermatically. This did not lessen the hemorrhage in the least. I then gave gallic acid in combination with aqua cinnamomi internally and small doses of morphine hypodermatically to allay the irritable cough. The arms and legs were then ligated, but the bleeding continued unabated. My patient was *in extremis* and I was in despair. I then injected $\frac{1}{60}$ grain atropine sulphate. The pupils were dilated within a few minutes, and as soon as this was perceptible the bleeding diminished. One hour after the first dose it was repeated and all other treatment stopped. A third dose was given four hours after the second, and to this $\frac{1}{16}$ grain morphine was added for the cough.

In the meantime Dr. Charles S. Starr, of Rochester, saw the patient with me and corroborated my diagnosis of a ruptured blood-vessel in a small cavity in the middle lobe of the left lung.

The atropine was continued in this case for three days, the doses being regulated by the effect on the pupils, constant and well-marked dilatation being kept up during the whole time. There was no bleeding after the second dose of atropine had been administered, although blood-stained mucus was expectorated for several days.

I have a record of three other cases which are in substance similar to this one. I will not take up your time by that which would be only repetition. In my later cases atropine was given from the first, and bleeding was promptly arrested in every case.

Conclusions.—1. The vaso-motor control over the pulmonary arterioles is nearly nil. 2. Vaso-dilators acting on the systemic blood-vessels can have no effect on the pulmonary arteries. 3. Atropine in full medicinal doses diminishes blood pressure by causing dilatation of the peripheral blood-vessels. 4. Atropine is, therefore, theoretically indicated in hemorrhage from the blood-vessels of the lungs.

A Fatal Case of Poisoning with Epsom Salts is reported by Dr. William Sang in *The Lancet* for November 7, 1891. The patient was a woman about thirty-five years of age, and the amount of the salts taken was four ounces.

An Insane Asylum in Florida.—There seems to be something wrong with the Jacksonville Insane Asylum if the telegraphic reports are to be believed. It is stated that a man who called recently to see his wife, a convalescent patient, was somewhat astonished to find her in the family way. Then another of the patients drowned himself in the tank from which the water-supply for the asylum was drawn, and the body was not discovered for more than a month. When found it was much decomposed, but it was simply removed, the report states, no effort being made to clean the tank in which it had lain.

Progress of Medical Science.

Intestinal Occlusion Treated by Electricity.—In *Mercredi Médical*, September 30, 1891, there is a record of such a case in the service of Dr. Semmola, of Naples. The patient, twenty years of age, well, strong, and of highly nervous temperament, fell a victim to an attack of indigestion from over-eating. This quickly disappeared under the influence of a milk diet. During convalescence an indiscretion brought on diarrhœa, which ceased the following day. Then attacks of pain came on suddenly, in veritable crises that soon evidenced a well-marked occlusion of the intestine. When ice, purgatives, injections, had all failed, laparotomy seemed the next expedient. But Dr. Semmola, when called in on the third day, made a diagnosis of paralytic occlusion, based upon the following facts: The abrupt onset of pain; its return by crises during which the transverse colon could be outlined; its appearance after diarrhœa; an accompanying retention of urine; and the neuropathic character of the patient. Electricity was applied, the positive pole in the rectum, and the negative following the course of the colon. The current was thus applied three times a day for five days, ten minutes at a time. At the end of the first day there was considerable improvement; on the third, normal evacuations; and from the fifth day, complete cure that has been permanent for two months.

Causes of Arterio-Sclerosis and Arterial Cardiopathies.—According to the *Mercredi Médical*, September 30, 1891, Dr. Huchard places the poisons of imperfect digestion among the many causes of arterio-sclerosis and arterial cardiopathies. Excessive meat diet, or game slightly cooked or of poor quality, throws into the economy numerous ptomaines that are imperfectly eliminated and are capable of producing poisonous effects hitherto ascribed to heart trouble, as vertigo, dyspnœa, etc. Such conditions are favored by renal insufficiency, that in turn becomes a cause of arterio-sclerosis. The town-dweller and the wealthy eat too much meat. Poor people and peasants eat less, but of such inferior quality that the result is the same, namely, an excess of ptomaïnes. For those showing predisposition to the troubles under consideration, well-cooked meat once daily, fresh vegetables in abundance, and milk, constitute an ideal diet.

Pathogenesis and Treatment of Scoliosis.—Dr. L. H. Petit, of Paris, according to the *Mercredi Médical*, September 30, 1891, thinks that scoliosis is due to some vice of nutrition that acts at the same time upon the three elements of articulation—upon the bones, ligaments, and muscles—beginning in arrest of development in some point of ossification in the body of the vertebræ. The primary cause of this condition is not rachitis. Subjects attacked with scoliosis are usually lithæmics, neuropathics. Among them, neurasthenia makes itself felt in all the joints, which show a generalized relaxation. If the spinal column seems to suffer oftener from deformity, it is simply because such an important deviation cannot possibly be overlooked. To lithæmia and neurasthenia is frequently joined mental overwork, bad habits of poise while studying or during play. Growth and the establishment of puberty are also a tax. Dilatation of the stomach is of frequent occurrence among lithæmics, neurasthenics, and those suffering from scoliosis. In itself it is a potent cause of debility. Treatment, exclusive of local or mechanical measures, consists in remedying as far as possible this dilatation, the lithæmic state, the neurasthenia, and menstrual disturbances.

Incontinence of Urine in Children.—In a recent issue of the *Annales de Médecine* Dr. Lyon gives some sound advice concerning nocturnal enuresis. Symptomatic incontinence must first be excluded. Then everything possible must be done to moderate cerebral activity, to break up the impulse or dream that prompts the act of micturition. Hygiene is of first importance. Drinks at night must be forbidden. Hydrotherapy is of great value. Antipyrin internally will often effect a cure. This failing, local irritation by electricity about the membranous portion of the urethra is an excellent remedy and a less violent procedure than cauterization. Moral suasion is helpful; and, as a last resort, hypnotic suggestion.

Experimental Pancreatic Diabetes.—According to the *Mercredi Médical*, September 30, 1891, before the French Academy of Medicine, Dr. Lancereaux exhibited for Dr. Thiroloix a dog which had undergone extirpation of the pancreas. The animal presented the typical condition of pancreatic diabetes, or what the French call thin diabetes. This condition had developed in thirty-five days after the operation. Glycosuria appeared within two days of the operation, ceasing twice for a period of one week, then was replaced by azoturia. In order to make the animal really ill, complete ablation of the pancreas was necessary, for simple ligation of Wirsung's canal had caused him no inconvenience whatever. The subject of pancreatic diabetes was then discussed by Drs. Germain Sée, Lancereaux, Ollivier, and Semmola. The foregoing interesting experiment Dr. Sée considered a valuable addition to those made by Minkowski, Mering, Hédon, and Lépine. It confirmed Dr. Lancereaux's earlier studies and discovery of the clinical picture of pancreatic diabetes. As the function of the pancreas upon general nutrition was as yet unknown, the substitution of azoturia for glycosuria in this experiment proved highly interesting. Not all "thin" diabetics could be called pancreatic. Three recent autopsies made by the speaker were negative in this particular. Dr. Sée recalled to the Academy his own experiments, made by the introduction of fluorhydzine. The remedies considered panaceas in the treatment of diabetes, Vichy and opium, were tried. Vichy proved unavailing, and opium hurtful. Dr. Sée strongly recommended antipyrin, and spoke of Dr. Panas's case that under the influence of this drug supported well the extraction of a cataract. In reply, Dr. Lancereaux said that pancreatic diabetes was a more precise term than "thin diabetes." There were several forms of diabetes: the fat form, or the diabetes of lithæmics that become fat at the end of the period of growth, with but little glycosuria, who were but slightly diabetic, slightly polyphagic, and who often live to the age of eighty. With these, diabetes was more a manner of being than a disease. Then there was pancreatic diabetes, and traumatic diabetes (Claude Bernard). Dr. Semmola objected to the interchangeability of the terms glycosuria and diabetes. The first was a symptom merely; the latter a terrible disease that might be nervous, traumatic, lithæmic, or alimentary in origin. There was either insufficient destruction of sugar or excessive production. Dr. Sée replied that, while agreeing with his confrère that an error in nutrition lay at the bottom of all diabetes, he thought the apparent fine condition of certain persons suffering from glycosuria should never mislead as to the gravity of the case, and referred to Dom Pedro, the late emperor of Brazil, who set up a serious gangrene of the foot while at Vichy, by simply trying to cure a corn. In summing up, Dr. Lancereaux said that slight and temporary diabetes was the same thing as permanent traumatic diabetes that soon became fatal, the difference lying solely in the degree of gravity, as in variola and varioloid. Earlier in the discussion Dr. Ollivier spoke of hereditary diabetes and of nervous emotional diabetes. The latter he had seen develop instantaneously upon a sudden loss of fortune. Fifteen years later the patient died of diabetic pneumonia.

Treatment of Puerperal Eclampsia.—In the *Journal de Médecine et de Chirurgie*, October 25, 1891, Dr. Dubost's views upon this subject are given. During the last three months of pregnancy it is absolutely necessary to examine the urine of every woman, without any exception whatever. Only in this way it is possible to meet

the exigencies of albuminuria and puerperal eclampsia. The examination must be made every fortnight, regardless of the fact that there may exist no subjective or objective symptoms pointing to albuminuria. Two things are to be considered in dealing with this condition, prophylactic treatment and the treatment of the disease when confirmed. The instant albumin is detected, the patient must be treated accordingly, throughout pregnancy, during confinement, and afterward until the last trace of albumin has disappeared. A milk diet is the treatment *par excellence* of albuminuria, and constitutes equally a sovereign prophylaxis against puerperal eclampsia. Tarnier and Budin state that women put upon milk diet always escape convulsions, and other observers confirm this. This simple precaution of exclusive milk diet would eventually exclude puerperal eclampsia, except in those rare instances wherein albumin precedes it by a few hours or a few days. When the convulsion declares itself, treatment depends entirely upon whether the woman is in labor or not. If not, all obstetrical methods are discarded and only medical measures are used. Of these, preference is given to chloral and chloroform. Chloral may be considered the specific in puerperal eclampsia. There are several ways to administer it, though not all are equally favorable. Large doses by the mouth produce serious irritation of the gastric mucous membrane, and at the same time are but slowly absorbed. Hypodermic injections are also objectionable. The best method of administering chloral is by the rectum, in the following form of enema :

Chloral hydrate..... ...	4 grammes.
Milk	100 grammes.
Yolk of one egg.	

This enema must be given with great care and precaution, for the patient is often in much motion. A syringe used for hydrocele is the one to employ, the extremity capped with a soft-rubber sound of eighteen or twenty calibre. This is anointed with borated glycerine and introduced high into the rectum and the enema gently given. In this way danger of injuring or perforating the rectum is averted. The injection is rarely expelled. If it is, it must be administered in the same way a second time. This rectal injection should always be given when, at the commencement of labor, there is agitation, restlessness, frontal headache, difficulty of vision, or pain in the epigastrium. It will often avert an eclamptic attack. If, at the end of three hours, the seizure continues and the temperature remains high, another enema may be given, containing as before four grammes of chloral. As many as fourteen, sixteen, or even eighteen grammes may be given in twenty four hours. The milk and egg render the drug less irritating, and these large doses are well supported. Chloroform is the next best agent in eclampsia. It is a powerful remedy, to be used while waiting for the action of chloral whenever a woman is in an eclamptic seizure. Often chloroform will ward off an attack that is imminent, and should be given on a handkerchief whenever such a catastrophe is suspected. Inhalations must be kept up until there is complete muscular relaxation. It is well borne and may be used when necessary for several hours, even for twenty-four hours, to keep the body in a state of relaxation. Because there have been no accidents is no excuse for neglect of any and every precaution. The physician should never leave the bedside of an eclamptic patient for any pretext whatever. The patient should be isolated in a warm room, far from noise or shock, and kept in half darkness. Every movement and examination should be avoided as far as possible, for even a touch may suffice to bring on an attack. It is necessary to sit by the bed to keep the woman covered and prevent her from falling out. If she strikes or attempts to do herself harm, the hands must be held by persons in attendance. Tying the woman or putting on a straight jacket impedes respiration and is a source of great danger. To prevent biting the tongue, a thick wad of rolled linen may hold it back of the dental arches. Wood or metal thus introduced may break the teeth. Drinks should not be given in porcelain or glass that easily breaks and thus becomes a cause of serious injury, but from a tin nursing-bottle. The attack once passed, the dose of chloral in the enemas is reduced, and these are decreased in number. Four grammes of chloral a day are soon sufficient. Purgatives, even drastics, or purgative enemata, every two or three days until convalescence is established. During labor, when there is a convulsion, these same precautions and rules are to be followed. But vaginal examinations are essential, for there is nothing to tell how matters are progressing except the touch, and the child may be born and smothered. Particular care must be given to the perineum, which is weak in all albuminurics and specially liable to great damage. When dilatation is complete, and not an instant before, the child must be delivered rapidly by the forceps. Naphthol may be used as an antiseptic. The perineum must always receive special attention, and the physician must be constantly on his guard against hemorrhage. Never consider a woman cured because puerperal convulsions are over. They may return at any moment. The urine must be examined daily and milk diet kept up until albumin has entirely disappeared.

Male-fern is not an entirely harmless remedy, though long in use and one of the best of anthelmintics. Dr. Eich does not favor the usual method of giving the drug fasting, since, when the stomach is empty the absorption of the toxic principles into the general system is facilitated and poisonous symptoms may occur. Several fatal cases of poisoning are reported. The ethereal extract contains poisons which act upon the central nervous system, a tetano toxine or tetanus-producing body playing an important rôle. The dose of ten grains or two and a half drachms should not be exceeded.—*Deutsche Medicinische Wochenschrift.*

Treatment of Abscess of the Breast.—In the ordinary way of treating an acute parenchymatous abscess of the breast coming on during lactation, the surgeon often finds that after one abscess is opened and temporary relief has been obtained, a second or third purulent collection forms, and persistent fistulæ cause the patient to despair. Dr. Boeckel recommends, as a means of avoiding this, to radically extirpate all the lobules implicated in the suppurative process. In the six cases so treated the following course was pursued : The patient being narcotized, the whole of the affected region was surrounded by two elliptical incisions from twelve to fifteen centimetres in length. The thinned skin and the diseased lobules were then removed, care being taken to make sure that no deep pockets already implicated should be left. Then, after disinfecting the operation field with the chloride of zinc and corrosive sublimate, the wound was brought together without drainage by means of deep and superficial sutures. The patients were completely cured at the end of nine or ten days.—*Gazette Médicale de Strasbourg.*

Myxœdema Treated by Injections of an Extract of the Thyroid Gland.—It has recently been considered as an established fact that myxœdema is due to loss of function of the thyroid gland. Improvement has followed the introduction beneath the skin of a portion of the thyroid taken from a sheep, and as the benefit was immediate it was argued that it must be due to the absorption of the juices by the tissues of the patient. Dr. Murray (*The British Medical Journal*, October 10, 1891) thinking it reasonable to suppose that the same improvement might result from injecting this fluid, or the extract of the gland, suggested this treatment some months ago, and has recently carried it out in a well-marked case, with decided improvement in his patient's condition. The freshly removed gland is cut up aseptically and placed in a test-tube, with one cubic centimetre each of pure glycerine

and a half per cent. carbolic acid solution. The tube is plugged with cotton wool and left in a cool place for twenty-four hours. The mixture is then squeezed out through a handkerchief previously dipped in boiling water. The fluid obtained is enough for two injections of twenty-five minims each, during the week, and each week the extract is to be made fresh. In the case treated, after three months œdema had markedly disappeared, almost normal speech had been regained, and the general condition was much improved. Dr. Fenwick has observed the action of thyroid fluid in two cases of myxœdema, and finds it a powerful diuretic. He thinks no effect is produced by the injections where the kidneys are in a healthy state. While much improvement was shown in his cases, he inclines to the opinion that the myxœdema depends on perverted renal function, and that the theory of the diseased thyroid is incorrect.

Peripheral Neuritis in Cancer.—Dr. Auché concludes a work on the existence of neuritis in cancerous subjects, in the *Revue de Médecine*, October, 1890, as follows: 1. Neuritis can develop, and in fact often does develop, in the course and under the sole influence of carcinomatous affections. 2. The situation of the neuritis is very variable, but in general the nerves are the more altered the farther they are away from the nerve centres. 3. These neurites are in relation with clinical symptoms which one must know to search for in such cases. 4. They are probably due to nutritive troubles and to alterations of the fluids and tissues which take place in the cachectic period of cancerous tumors.

Diagnosis of Bladder Tumors.—Dr. Guiard points out some features of hæmaturia which may aid in establishing the diagnosis without digital examination or exploratory incision. Prostatic tumors are scarcely ever accompanied by hæmaturia; renal tumors very generally are. Renal hemorrhage is quite often only of short duration, small in amount, and recurs at long intervals. At times there is an alternation of clear and bloody urine in the same day, a condition never seen in hemorrhage due to tumors in the bladder. Renal hemorrhage gradually diminishes and finally disappears. The opposite is seen in bladder tumors. In washing out the bladder if the last drops consist of pure bright blood, it speaks for tumor of the bladder. Elongated clots, rarely found, are probably formed in the ureter, especially if pains like renal colic have preceded their discovery. Small blood cylinders may be casts of the efferent kidney tubes. Hypogastric palpation alone usually shows nothing, but after the bladder has been emptied Guyon's method of *ballottement* shows the smallest increase in the size of the bladder. By pressing the anterior hand deeply with successive expirations, the extent and thickness of a bladder tumor can be appreciated.—*Archives Gén'rale de Médecine*, October, 1891.

Prevention of Pyo-septicæmia in the New-born.—Professor Epstein says, in the *Jahrb. für Kinderheil.*, No. 31, that much may be done to diminish the death-rate from pyo septicæmia in the new-born, which is too common even in private practice and under the most favorable external surroundings. Cases are very rare in which septicæmia is acquired in utero or during parturition. The most common entrance for septic matter is the umbilicus. The danger is, of course, greatest during the first few days after birth, when the navel presents the conditions of an open wound. Prophylaxis must begin with the most careful treatment of the cord. The stump should be well cleansed and surrounded with carbolized gauze, with the idea of securing mummification at the earliest possible moment. All forms of moist dressings should be avoided. Antiseptic powders are not favored, as sometimes they produce a fungous growth. Free access of air to the stump has been found to hasten the process of drying and healing. The hands of the physician and nurse should be scrupulously clean when dressing the cord. For the first baths such an antiseptic solution as that of permanganate of potash is recommended. Too often and too severe washing of the mouth is a frequent cause of aphthæ. Dirty fingers or dirty instruments must never be put into an infant's mouth in case of asphyxia, etc. One drop of a two per cent. solution of nitrate of silver should be instilled into each eye of the new born, in private as well as in public practice, as a preventive of blennorrhœa.

Gastric Headache.—Dr. Westphalen has found that toxic substances in the stomach under certain conditions are capable of producing, through absorption, disturbances of circulation in the central nervous system and its associated parts which result in headache. A complete absence of hydrochloric acid in the stomach contents was found, and when this acid was prescribed complete recovery followed. The theory advanced for the beneficial action of this drug is that ptomaïnes or toxines of micro organisms exert an injurious influence only when there is a deficiency in the quantity of free mineral acid in the stomach. Headache may also be prevented in such cases by administering the acid directly after the patient has eaten articles which have previously always been followed by headache. The nature of the noxious substance is at times obscure, as in instances where indigestion, headache, and urticaria follow the use of chocolate or strawberries, but in such cases also hydrochloric acid acts well.—*Berliner Klinische Wochenschrift*, No. 37, 1891.

Yellow Fever is raging at Santos and the quarantine officers examine all the steamers arriving at this Port from Brazil with special care.

Punishment of Abortionists in France.—A trial which has been going on at the Palais de Justice, in Paris, for twelve days, in which Marguerite Thomas and Abélard Fleury, with forty-six accomplices, were charged with illegal obstetric practice, came to a close recently. Thomas was sentenced to twelve years' hard labor, and excluded from Paris for a further period of eight years. Fleury was sentenced to ten years' solitary confinement. Two other women were sentenced to two years' imprisonment, and the remaining forty-four were acquitted.

The Debility following Influenza is said to be greatly benefited by anacardium occidentale (cashew nut).

Eye-lotions of Boric Acid for Influenza.—Dr. Richard Sisley, in a paper read before the International Congress of Hygiene and Demography in London last summer, quoted Dr. Bezly Thorne, who recommended that the eyes of people exposed to infection should be bathed with a solution of boric acid, and found that none of those who adopted that practice suffered from the disease. The recommendation was founded on the theory that the poison of influenza is absorbed by the conjunctiva.

Harvard Medical Graduates will be interested to know that Bulletin No. 1, containing a report of the first annual meeting of the Harvard Medical School Association, held in Boston June 23, 1891, has been published, and will be sent to any graduate on application to the Secretary, Dr. Robert W. Lovett, 379 Boylston Street, Boston, Mass.

A Double-faced Woman.—Women with two faces are often heard of, but they are rarely seen presenting both faces for inspection at the same time. A Mexican journal announces the following curious condition: "A lady with a normal face in its normal situation has also a reproduction of a human face upon the right thigh. There are two perfect eyes and a mouth filled with teeth. If the cheeks are pulled down the eyes open. Apart from this abnormality the lady is said to be well formed." Probably maternal impressionists might claim that this freak had a gossipy mother.

MODERN TREATMENT OF PNEUMONIA.

THE result of interviewing prominent French physicians upon the subject of pneumonia and its treatment, is given in substance in the *Gazette des Hôpitaux*, November 24, 1891. Opinions are widely divergent, and at the same time sufficiently interesting. Preparations of antimony are in general disfavor, while injections of caffeine are held in high esteem. No one pretends to have any set rules, symptoms or complications receiving attention as they arise. As agents of value, kermes mineral, wet cupping, blisters, cold baths, alcohol, kola, tea, coffee, camphor, digitalis, and subcutaneous injections of ether are advocated. Those who incline to a middle course affirm that pneumonia can take care of itself in many cases, and get along without drugs, medical interference being reserved for emergencies. This is the view of Dujardin-Beaumetz, Becquoy, and Rigal. Simple pneumonia in children is never fatal, according to Hutinel. The consensus of opinion favors the idea that to combat asphyxia, strengthen the heart, sustain the patient, and to administer milk as both diuretic and aliment, constitutes the best there is of modern treatment.

Systematic venesection is now obsolete. One authority seems to regret this, Professor Cornil, late chief assistant to Boillaud. The statistics of Boillaud's clinics, he affirms, show better results than are obtained nowadays, in part due, possibly, to the different character of pneumonia at the present time. It is well to bear in mind that reports of cases subjected to no treatment whatever, in Paris and Vienna, show better results than any similar number wherein venesection has been practised. Wet cups are applied over the seat of earliest inflammation by Proust, Peter, and Descroizilles. Blisters are also advocated, by Cornil at the outset, Dujardin-Beaumetz when fever has disappeared, and also by Becquoy toward the close of the disease. Ferrand considers them valuable, and Proust thinks they are useful in relieving congestion and getting rid of morbid products. In the case of children, one or two blisters are applied by Descroizilles. On the other hand, Muselier, Landouzy, Faisans, and others look upon them as not only useless but positively hurtful.

In regard to internal remedies, Dujardin-Beaumetz looks upon kermes mineral as unsafe, though tartrate of ammonium is given by Peter, Becquoy, and Danlos. But this style of treatment is completely ignored by Montpallier, Andhoi, and Faisans. Subcutaneous injections of caffeine, from fifty centigrammes to three grammes a day, are employed by Moizard, Huchard, Hutinel, Legroux, and Dujardin-Beaumetz. The latter prefers kola, coffee, and tea to alcohol, though this he uses during convalescence. Alcohol is administered by Peter to the aged and the weak; when there is fever by Ferrand; and to sustain the heart by Moizard, Proust, and Faisans, with the addition whenever necessary of caffeine and digitalis. As analeptics, Ferrand favors acetate of ammonium, tincture of arnica and of bryonia, camphor, and musk. To combat fever quinine is used by Becquoy, Moizard, Legroux, and Faisans. Cold baths are beginning to find favor. They are advised by Rigal in nervous phenomena incident to the nephritis of pneumonia. When there is high fever in children Hutinel finds them of advantage; Montpallier thinks well of them, and Andhoi has all his patients bathed in tepid water, with or without soap, for cleanliness rather than for therapeutic effect. Saline purgatives are used to overcome gastric disturbances, ether subcutaneously to combat collapse, and ergot to hasten tardy resolution. In fact, the modern treatment of pneumonia everywhere may be briefly stated as a mixture of common sense and individual peculiarity, the first being the largest ingredient.

SOME RECENT VIEWS ON LUPUS.

WHILE the consensus of opinion is almost unanimous in favor of the tuberculous nature of lupus, there still remain many standpoints from which medical thinkers look upon the disease, and it is always interesting, and often profitable, to note their views.

In a discussion of lupus which took place at the annual meeting of the British Medical Association, Dr. Payne draws attention to certain points which still admit of controversy.

Lupus has occasionally been attributed to traumatism, but in such instances there must either have been something abnormal in the tissues of the patient, or some specific infection is introduced into the wound. Everything points to a specific irritant, and the structure of the growth warrants the same conclusion. The history of the disease, both clinical and pathological, the speaker thought, would show that there must be a persistent, and therefore a living, irritant which keeps up the granulation growth.

No point has been more debated than that of the relationship which lupus bears to tuberculous or scrofulous disease in the same subject. In the experience of Dr. Payne, while the majority of lupus patients are healthy in other respects, about one in four present some other manifestation of tubercle, such as joint disease, phthisis, or scrofulous glands.

Although this proportion is much larger than that given by most observers, it does not have such a great bearing on the question after all, for we can conceive it quite possible for one organ or region of the body to be affected and other organs escape. In regard to family history, the speaker goes on to say that he has found an even greater proportion of tuberculous affections, and finds that they are indeed more frequent in the parents or relatives than in the patients themselves. If this personal experience can be established as a general princi-

ple, it would lead to the suggestion that lupus is often a manifestation of hereditary tuberculosis. In this connection it is interesting to note Baumgarten's recently advanced view, that the bacillus may be directly inherited, like the virus of syphilis, from one or the other parent. Drysdale believes that this theory is tenable for a certain number of cases of lupus, while several gentlemen who took part in the discussion of Dr. Payne's paper, including T. Calcott Fox, agreed that a family history of tuberculosis was especially frequent in lupus cases.

It is generally stated, however, that lupus itself never occurs in two successive generations; but this is evidently an erroneous statement, for the author has himself seen it in parent and offspring. Another instance, where instead of "never" one should substitute "hardly ever," is in Mr. Hutchinson's statement that lupus never gives rise to infective gland disease, since Leloir has found that adenopathies frequently occupy the lymphatic structures leading from the lupus, and Fox states that lupus can undoubtedly secondarily infect the related glands and lymphatics, and, after long years, the viscera.

That infection may take place in the opposite direction would also appear probable from the author's experience as well as that of Radcliffe Crocker, though the bacillary growth of scrofulous glands usually dies off when it reaches the surface, and only exceptionally extends along the skin in the clinical form of lupus. The experience of a number of gentlemen present was to the effect that the association of lupus with other tuberculous lesions was not the rarity which it was usually believed to be, but was on the contrary not infrequent. Fox has shown by the statistics of eighty hospital cases of true lupus, that scrofulous or tuberculous lesions of the skin, bones, glands, or joints were frequent complications.

Lupus differs from other forms of tuberculous disease in its slow and chronic process, its feeble infectivity, and the paucity of bacilli usually found; and the author attributes these characteristics, in a measure at least, to the comparatively low temperature of the skin, which offers an unfavorable condition for the development of the bacilli, being about twenty degrees lower than that presented by internal organs. The author sees no reason for making any broad distinction between lupus and inoculated traumatic tuberculosis; while Pye-Smith still believes in such a distinction, though admitting the same bacillary origin for both. Fox points to the failure of attempts to reproduce lupus as a weak spot in the argument, but it must be borne in mind that Mr. Eve has by inoculation of lupous tissue in a rabbit's ear produced what was apparently a true lupus differing from inoculated tubercle. It will thus be seen that, while more is known about the nature of lupus than formerly, there are many points on which observers still differ; but as more attention is being paid at the present time to tuberculous diseases in general than probably ever before, it is more than likely that some of these at least will soon be definitely settled.

The Consumption of Eggs in Paris is something enormous. According to a municipal statement, the metropolis consumed last year no less than 23,000 tons of eggs —equal to about 9½ kilos *per capita*, or 147 eggs.

PAIN IN HEART DISEASE.

Very often pain experienced by those suffering from heart lesions is due to pleuritic trouble, to the rheumatic diathesis, or to some functional nervous disturbance. At the same time pain in the left half of the thorax always suggests a possibility that its relation to cardiac abnormity is more than coincidence. The *Lyon Médical*, November 1, 1891, quoting from another journal, gives in substance Dr. Nothnagel's recent contribution upon this subject, based upon the study of four hundred and eighty-three cases, all neuropathic; painful precordial affections and pericarditis being excluded. Cardialgia is of extreme frequence in aortic insufficiency and stenosis, and rare in mitral regurgitation. Leaving out sclerosis associated with obliteration and stenosis of the coronary vessels, the author finds that in muscular cardiac defects pain is frequent only in arterio-sclerosis with hypertrophy of the heart. The clinical aspect in this case is identical with symptomatic cardialgia associated with valvular disease. The pathogenesis of this pain is not discussed, our knowledge of the heart's nervous mechanism being as yet too circumscribed for the establishment of any theory. The extreme frequence of cardialgia in aortic affections seems to indicate that its origin lies in the artery itself. Diseases of the arteries are always extremely painful. This accords with the fact that in cardiopathics in general there are frequent lesions of the coronary vessels.

THE MEDICAL TREATMENT OF CYSTITIS.

In a paper read before the Philadelphia County Medical Society recently, Dr. James Tyson gives a plain and practical account of the best way to treat acute and chronic cystitis by medical means. In his article Dr. Tyson disposes very summarily of some therapeutical measures which are commonly thought to be useful, clearing the ground for what he believes is rational treatment.

As to acute cystitis he says: "Acute cystitis is far less commonly met by the physician than the chronic form, while its treatment is far simpler, and, I may add, more satisfactory, at least so far as the removal of the acute symptoms is concerned. Rest in bed is a primary and essential condition. Leeches to the perineum should be applied more frequently than they are. A poultice to this same region and over the abdominal region is always useful, while a brisk saline cathartic should never be omitted.

"As the feverish state which always accompanies cystitis is more or less constantly associated with a scanty urine, concentrated and irritating to the inflamed mucous membrane, it is desirable at once to increase the secretion, and thus dilute it. Copious libations of pure water, to which the citrate or acetate of potassium is added, in fifteen to twenty grain doses for an adult, should be allowed. The ordinary spirits of nitric ether in two-drachm doses every two hours is an admirable adjuvant, and may be combined with the officinal liquor potassii citratis, which contains about twenty grains of citrate of potassium to the half ounce. Formerly the mucilage of flax-seed, or flax-seed tea, was much used as a diluent menstruum for the diuretic alkalies indicated, but I am

doubtful whether it is any more efficient than a like quantity of water.

"Where there is much pain and straining, as is often the case, especially where cantharides is the cause of the inflammation, opium is indispensable, always in the shape of a suppository, half a grain to a grain of the extract being thus administered, or a proportionate amount of morphine. Iced water injections into the rectum, or pieces of ice similarly applied, are very efficient in allaying the pain and irritation where additional measures are needed."

In chronic cystitis there are three indications to be met: First, to lessen the irritating qualities of the urine; second, to medicate the inflamed surface; third, to get rid of the pent-up inflammatory products. To meet the first indication one or two quarts of pure water should be drunk daily. It is, as Dr. Tyson says, a mistake theoretically to give alkaline waters or alkalies, yet practically in our opinion one sometimes finds good results from them. The best drug, as a rule, however, is benzoic acid, given in doses of thirty grains a day. To meet the second indication and medicate the surface of the bladder one may use both drugs and injections. Dr. Tyson discards entirely all the commonly used preparations, such as buchu, pareira brava, triticum repens, etc. He relies entirely on the balsams, and in particular on sandalwood oil, of which about eighty minims a day should be given. Boric acid, resorcin, and naphthalin may also be tried. Internally injections of tepid water twice a day should be used, about four ounces being injected at a time. After a while salicylate of soda, in the proportion of a drachm to the pint, may be employed. If there is much pus alum is to be added, and if there is a foul odor very weak solutions (1 to 25,000) of bichloride of mercury.

"Anodynes," Dr. Tyson adds, "are indispensable in many cases of cystitis to relieve the patient of extreme pain and the frequent desire to pass water, which are the result of the same cause. Opium and its alkaloids are the most efficient, and they are best introduced by the rectum. There appears to be no absorbing power for opium at least, and there is no use in attempting to use any anodynes by that channel."

Cocaine, from which so much might reasonably be expected, has failed of its purpose in Dr. Tyson's hands. He has injected as much as two ounces of a two per-cent. solution into the bladder without effect, except to produce some of the symptoms of cocaine poisoning. Most disappointing, too, has been the use of cocaine to remove the exquisite tenderness of the urethra which sometimes attends this condition, and is a serious drawback to the use of the catheter.

Where there is greatly enlarged prostate, catheterization is indispensable, and is attended often with the most happy results. It is often too long deferred because of the natural repugnance to the use of the instrument.

A Successful Case of Bone-grafting is reported from Allahabad, a solution of continuity in the anterior layer of the frontal sinus having been induced to take on osseous repair by sprinkling the surface with "small fragments" of the hip-bone of a newly killed dog.—*Medical Press.*

HOW TO LESSEN INSANITY.

The *Journal of Mental Science* for October, 1891, tells us how. This knowledge is embodied in Article 4 of a report on the care and treatment of the insane, formulated by a committee appointed by the Medico-Psychological Association of Great Britain and Ireland. The first thing to do is to avoid unwise marriages, and the next is to obey carefully all physiological laws. Moderation in all things is another factor. Judicious training and education, both mental and physical, are imperative necessities. Conditions of life and occupations that counteract morbid tendencies are the ones to be adopted. And last, but not least, is the preservation of a calm and equal mind amid the cares and perplexities of life. In other words, the speedy arrival of the millennium will lessen insanity.

Those earnest, honest men over in England who put this report into shape never meant to be funny, yet the whole of Article 4 bears a striking family resemblance to a saying of Greenough, the sculptor, to the effect that happiness consists in health, wealth, and requited affection. The directions for lessening insanity and the definition of happiness sum up about all there is of ideal human life.

THE REVIVAL OF SYMPHYSEOTOMY.

An interesting crusade has recently been begun in Paris by Dr. Spinelli in behalf of symphyseotomy. Dr. Spinelli is a pupil of Professor Morisani, of Naples, who is known as the most skilful and experienced advocate of this measure.

Symphyseotomy for the extraction of the living fœtus is an operation which has never obtained a footing in any countries but Italy and France; the former country, and in particular Naples, is the especial home of it. Up to a few years ago 115 operations had been done in Italy, 32 in France, a few in Holland, Belgium, and Germany, but none whatever in the United States. (Harris.)

The operation as originally devised by Sigault in 1777, and as subsequently carried out, was attended with very poor results, and it fell into merited disuse. Among 86 cases 29 women and 45 infants died.

Since the operation was revived in Naples, in 1866, the results, owing to improved technique and better judgment in selecting cases, have been much more satisfactory. The mortality of both the mother and fœtus is now less than twenty per cent.

The lessened risk from the Cæsarean and Sänger operations has no doubt prevented the labors of Morisani from being more widely utilized. It is admitted also that symphyseotomy has only a narrow range of usefulness. It covers about the same field as craniotomy. According to Dr. Harris, it should never be tried when the available conjugate diameter is less than $2\frac{5}{8}$ inches, and it is contra-indicated in cases in which there has been disease of the sacro-iliac symphysis.

The question arises, however, whether symphyseotomy should not be tried when the diameter ranges from $2\frac{1}{2}$ to $3\frac{1}{4}$ inches, since by it the child may be saved.

Professor Morisani has decided to place the matter before the International Medical Congress to be held in Rome in 1893, and in the meanwhile to call the atten-

tion of specialists to it in order that they may be prepared to discuss it in due time. For this reason Dr. Spinelli has gone to Paris, where he has, we are told, been well received.

On November 16th he gave an experimental demonstration before a number of prominent obstetricians.

We trust that American physicians will take a proper interest in the matter.

THE HEADACHES OF CHILDHOOD.

Growing pains are more of a myth in regard to origin than in point of discomfort. The latter is very real. Headaches of the period of growth, so called, Dr. Jules Simon thinks very often due to causes other than those associated with organic development. This matter is treated at length in the *Journal de Médecine et de Chirurgie*, November 10, 1891. Headache in pale, puffy, sleepy eyed children, coming on after meals, is a digestive headache due to dyspepsia, that may be brought into existence by bolting the food, eating too frequently or at hours unwisely chosen, or too heartily at supper-time, or too near the hour for going to bed. Such headaches are benefited by reducing the evening meal to the minimum, sometimes suppressing it altogether, by warm drinks, by abdominal massage, and electricity applied to the abdomen. There is one kind of headache that is purely nervous, the headache of environment, so to speak, due to educational methods that result in a sort of perpetual exhaustion. This headache is worse toward evening. It may also be an expression of one of three distinct nervous disorders in this incipient state, of hysteria, epilepsy, and chorea. The epileptic headache Dr. Simon considers easy of recognition, for the pain comes on periodically and lasts an hour or two ; often the character undergoes temporary change, and the patient is for the time incapacitated. Bromide acts well in such cases, also belladonna. These failing, the polybromides are usually successful. Hygiene is the mainstay. It must ever be borne in mind that children suffering from nervous headache are very sensitive to cold, and that they should be clad accordingly.

The choreic headache is difficult to diagnosticate at first, especially when the movements are but slightly accentuated. Antipyrin, which Dr. Simon calls the remedy for chorea, given in large doses will cure this form of cephalalgia. The rheumatic or uric-acid headache in children is usually an expression of gouty or rheumatic hereditary tendencies. Two interesting cases are cited—one a boy who appeared to have meningitis, yet recovered in a surprisingly short time under treatment of which an important element was bromide of potassium. The other, a girl fifteen years of age, suffered from persistent headache with congestive crises. Bromide was tried three months without avail. Small doses of salicylate of soda, followed by colchicum and valerian, induced rapid improvement in a remarkably short space of time. The rheumatic or uric-acid headache in its clinical aspects presents certain special characteristics. It is often accompanied by supra-orbital or post-cervical neuralgia, by joint troubles, and shifting symptoms that find expression in different parts of the organism. The urine is concentrated, cloudy, and contains urates in abnormal quantity. There is often profuse sweating without apparent cause, and attacks of colliquative diarrhœa. The foregoing are diagnostic points. Pain is first to be overcome. But the true remedies are those that relieve congestion, as the bromides, salicylate of soda, and colchicum. Diet plays an important part. Our French authors consider children subject to rheumatic headaches often sluggish in mind and body and indifferent to exercise. This they must be forced to undertake. Stimulation in the way of dry rubbings, and rubbings with warm liniments, are advised.

Even very little children do not escape malarial poisoning that gives rise to violent headaches. Quinine and hydrotherapy will cure this condition, that is, intermittent, accompanied by neuralgia, sweating, and general irritability. Other headaches due to poisoning are those that follow the protracted use of drugs, such as belladonna, opium iodide of potassium, and digitalis.

News of the Week.

The New York State Board of Medical Examiners.—If deliberation is a mark of a judicial mind, the members of this Board should be on the Supreme Bench. An examination of candidates was held in the Cooper Union, in this city, on the four days ending November 13th, and up to the present writing these unfortunate men are still waiting to learn whether they may lawfully practise medicine in this State or not. To the unofficial mind the keeping of candidates in suspense for six weeks seems little short of cruelty, and it is difficult to imagine any plausible excuse for such delay. We cannot congratulate the Board on the success of its first attempt, but possibly it may learn to move a little less slowly in time.

The Decline of Matrimony in England.—The decline of matrimony in England has of late years been very marked, more especially among the middle and upper classes. Nor are the revelations that are occasionally made in the divorce court of a nature to encourage the more prudent and eligible young men, and those who would make the best husbands, to be in any hurry to enter into the enjoyment of connubial bliss. It is some relief to middle-class families overburdened with an excess of daughters that the opportunities for girls earning their own living appear to be on the increase; but the competition for paid employment acceptable to young ladies of the middle classes is every day growing more severe. The prospects for middle-class girls in the immediate future appear, therefore, to be anything but bright, except to those who are not afraid of work. There are thousands of young men wanting wives at this moment in Australia and America, where there are few wives to be had. There is a career open to the surplus female population of England, if they can only manage once to get to the other side of the globe.

The Influenza Violently Epidemic in Berlin.—In connection with the prevailing epidemic of influenza at Berlin, a curious and somewhat disquieting fact has been reported by Professor Renvers to the Berlin Therapeutical Society. It is to the effect that in the clinical wards of the Charité Hospital, under the superintendence of Pro-

fessor Leyden, the disease has reappeared in the same rooms that were occupied by influenza patients in 1889. This seems to show that the interval of a whole year has not sufficed to get rid of the infection.

Dr. Rogers Pacha, Chief of the Medical Staff of the Egyptian army, has been appointed to succeed Dr. Greene Pacha as head of the Egyptian Sanitary Service.

Anti-Hypnotism in Belgium.—The Belgian Chamber of Representatives is discussing the Government bill, which has been brought forward in response to the wishes of the Belgian Royal Academy of Medicine. It is introduced to prohibit public exhibitions of hypnotism, as well as to anticipate and put down abuses which might arise from the practice of hypnotism.

Metropolitan Medical Society of New York.—At the annual election of the Metropolitan Medical Society the following gentlemen were elected officers for the ensuing year: *President*, Dr. Frank A. McGuire; *Vice-President*, Dr. William Cowen; *Recording Secretary*, Dr. F. F. Marshall, and *Corresponding Secretary*, Dr. Henry S. Stark.

The Alumni Association of the Mount Sinai Hospital celebrated the first anniversary of its existence with a dinner on December 7th at The Arena. Covers were laid for thirty, and a happy evening was spent in recalling the incidents of its old interne days. Dr. Alfred Meyer presided.

State Medical Examinations in Ohio.—Pursuant to a call issued by the Cincinnati College of Medicine and Surgery for a delegated convention of the medical colleges of the State of Ohio, held at Columbus, on December 3, 1891, representatives of the following faculties were present, viz.: Starling Medical College, Toledo Medical College, Pulte Medical College, Columbus Medical College, Medical Department of the National Normal University, College of Physicians and Surgeons of Columbus, Woman's Medical College of Cincinnati, and the Cincinnati College of Medicine and Surgery. Dr. Starling Loving was elected Chairman and Dr. Charles A. L. Reed, Secretary, who presented the following:

Resolved, By the Medical Colleges of Ohio, in convention assembled, that the Legislature be and is hereby requested to enact a law which shall embody the following features, viz.:

1. The creation of a board or boards of medical examiners, in the composition of which equitable and just representation shall be accorded to the various recognized denominations of medical practice. 2. The examination of all candidates for the practice of medicine holding diplomas hereafter issued by medical colleges which shall be deemed in good standing by the board. 3. Exemptions from examination to extend only to those who at the time of the enactment of this law shall be recognized as legal practitioners within the meaning of existing statutes; but all legal practitioners shall be required to register. 4. A penal clause which shall secure the enforcement of the foregoing provisions.

On motion by Dr. Scoville a committee consisting of Drs S. S. Scoville, T. C. Hoover, G. W. Mayhugh, and Charles A. L. Reed, was appointed to confer with the Legislative Committee of Cincinnati for the purpose of securing such changes in the bill proposed by that committee as to make it conform to the resolutions adopted by this convention.

A Claim that Influenza is Contagious.—In his interesting work on "Epidemic Influenza," Dr. Richard Sisley claims that the cause of the disease is probably a microscopic organism, that it is contagious and is chiefly if not entirely spread by contagion. In proof of his theory of contagion he cites cases that show that influenza spreads from the sick to the sound; that isolated cases of influenza precede an epidemic; that influenza spreads along the lines of human intercourse; that prisoners and other isolated persons often escape influenza, although the disease may be raging in the town in which the prison is situated. He claims that the local health board should be notified of cases of influenza just the same as in cases of scarlet fever or diphtheria, and that laws should be passed making such notification compulsory.

Obituary.

R. A. KINLOCH, M.D.,

CHARLESTON, S. C.

The decease of this distinguished surgeon removes one of the most able medical men which the South has produced. Inheriting from his Scotch ancestry that most rare of all intellectual qualities—good common sense—he was carefully educated at a time when a rapid passage through the schools was regarded as an ample medical education. After finishing courses of instruction in his native State, and graduating from the University of Pennsylvania, he spent two years in the medical centres of Europe, chiefly in Paris, London, and Edinburgh, for the purpose of broadening his knowledge.

Dr. Kinloch early developed a preference for surgery. The writer's first clinical instruction in this branch being obtained from him, he is free to say that no teacher to whom he has since listened, excelled him in clearness of presentation of the salient diagnostic points, nor in skilful manipulation.

To Dr. Kinloch is given the honor of having made the first resection of the knee-joint for chronic disease in this country. By his numerous and daring surgical exploits he won the position of standing at the head of his branch in his own and in the neighboring States.

During the late war Dr. Kinloch served as Medical Director of Hospitals for South Carolina, Georgia, and Florida, and as a member of the board for examining candidates for the medical department of the Confederate army.

Although he lacked that personal magnetism by means of which many less gifted men have reached eminence, he endeared himself slowly, but surely, to those who knew him well by his striking simplicity, his modesty, his candor, and his genuine kindliness of heart. He attained a lofty position in medical and social circles purely by reason of his absolute worth, true manliness, and excellent professional skill.

Dr. Kinloch's life was greatly saddened of late by the sudden death of a gifted son, in a railroad accident, which seemed to throw a pall over his life. Nevertheless, he did not relax from his self-imposed labors for the honor and advancement of his chosen calling.

Although well advanced in years, he was an active member of many medical societies, and often journeyed long distances; leaving his large practice to attend meetings of the American Surgical and other societies.

The life of this sterling man, illustrating the possibilities of a true physician's work, may be held up as an example most worthy of emulation.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, October 22, 1891.

EGBERT H. GRANDIN, M.D., CHAIRMAN.

Treatment of Pelvic Sinuses.—DR. W. GILL WYLIE presented a specimen and related the case in its relations to the question of how to treat sinuses the sequel of old pelvic inflammation, including salpingitis. Like other operators, until three years ago he did not encourage these patients to submit to an operation, having doubt whether he could deal with them successfully. From the experience gained last winter, he believed he could now treat them with as little risk as he could a case of ordinary salpingitis. In the case of the specimen presented, the patient had had a miscarriage some months ago, and developed what her physician supposed to be a cellulitis or peritonitis. There were several attacks, pointing pretty plainly to local peritonitis. This subsided, and she had a uterine hemorrhage, for which a physician, not a specialist in gynecology, curetted her, and soon afterward she suffered from chill, high temperature, and signs of local peritonitis. Dr. Wylie was called about the fifth day, and found on the left side of the uterus a tumor as large as one's fist, very tense, painful, and the uterus fixed. It was evidently an abscess within the peritoneum, around the left tube and ovary. He suggested an operation, but was in doubt whether it was best to tap per vaginam or to open the abdomen. The patient objected to an operation at that time, and when he came back from the country, about two weeks later, the abscess had burst into the rectum. The temperature fell, and the patient felt relieved until the tumor ceased to discharge and refilled. When it again discharged per rectum there was again relief. She entered the hospital, Dr. Wylie felt fluctuation posterior to, and on a plane with, the left broad ligament. But when such a tumor had emptied into the rectum, one was not likely to find it full enough of pus again to make vaginal puncture safe. He knew of two cases where the puncture had resulted in death, the trocar entering the broad ligament or in front of it. If, after waiting a sufficient time, the cavity did not refill and make it safe to puncture by the vagina, he opened the abdomen and was then able to guide the trocar introduced through the vagina so that it would not penetrate the intestine. Drainage thus established by the vagina sometimes resulted in absolute cure, but in four cases out of five an operative procedure would have to be undertaken to destroy the fistulous tract. After drainage had been established in the manner just mentioned, the radical operation could be undertaken with much less danger of sepsis. It consisted in removing the cause of the pus accumulation—for instance diseased tubes and ovaries—and dissecting out the pyogenic membrane; perhaps also in closing the rectal opening. In puncturing, the trocar was so constructed that a piece of it remained in the opening to act as a drainage-tube, and was fastened to the cervix to prevent it from falling out. This was left in four or five days, when a larger tube could be inserted through the fistulous tract left by the former, making thorough drainage. In the case related the abscess was in the ovary, the pyosalpinx remaining undisturbed. This was learned subsequently, when he performed laparotomy and removed the tube and ovary, together with the abscess-sac and lining of the fistula, by means of the finger-nails. The greatest care must be exercised on reaching the junction of the sac and opening into the rectum, lest the gut be torn. Formerly he would have thought it imperative to find the old rectal opening and close it; now he did not. In case, however, it came readily into view, its edges could be trimmed and united. The sac should be thoroughly cleansed before its removal was undertaken. The death-rate in his cases had not been much greater than in cases of ordinary pyosalpinx.

Hemorrhage, not Shock.—Dr. Wylie presented a second specimen, which was of interest intrinsically, as well as from the fact that it was the first death in his last seventy laparotomies. Incidentally it led him to the remark that he would rather undertake a formidable operation, in which there was danger of sepsis, in the summer than in the winter. This patient was forty-four years of age, had been an invalid for years, giving a history of dragging pains in the pelvis and of hemorrhage. He found the uterus enlarged, presumably studded with small fibroids, and to its right was a tumor somewhat smaller than one's fist, irregular in shape, seemingly a sarcoma of the broad ligament. Laparotomy showed the uterus studded with small fibroids, the tubes and ovaries healthy, except that the left one was somewhat atrophied. The tumor was underneath the broad ligament on the right side, the tube and ovary above it, the uterus to its right. He remarked to those present at the operation that it felt as if it might be the kidney, the right one, since it was on the right side. It was not floating, but was fixed in the right broad ligament. On enlarging the abdominal opening, however, and making further search, he was surprised to find the right kidney in place, and equally surprised to find no kidney on the left side. The operation was completed by removing the appendages and the tumor, which was a second right kidney, somewhat misshapen. He took the precaution, which he usually did after cutting off the diseased tissues, of retying the stump, but he did not wait, as was his custom, to see whether any blood collected in the cavity, indicating oozing from some unexpected source. The operation was performed in the morning, and at midnight there being sweating, restlessness, and rapid pulse, he was sent for, and opened the abdomen. In years past he would have thought of shock, and stimulated the patient, but he expected at present, under such circumstances, to find hemorrhage, and it was so in this case. The bleeding-point was a vein which he had accidentally punctured with his needle while ligating the stump. The vein lying deeply, the loss of blood was not observed when he lifted the stump at the time of the operation. The patient died five or six hours later.

Dr. Wylie said he was convinced that many cases of death heretofore reported as due to shock were really due to concealed hemorrage, and that life might be saved by reopening the abdomen. And if hemorrhage did not kill directly, the escaped blood formed a favorable nidus for the development of germs which may have been in the abdominal cavity before the operation, or introduced when it was performed.

DRS. MURRAY, LOCKE, and GRANDIN expressed their appreciation of the remarks of Dr. Wylie with regard to the use of the finger-nails, first emptying the sac of pus, danger of manipulating the rectal opening, after-inspection for hemorrhage, etc. The Chairman remarked that shock had militated perhaps most against success in abdominal surgery, and if it consisted, as he had understood Dr. Wylie, in internal hemorrhage, we now had a positive indication for treatment in these cases, namely, to reopen the abdomen and check bleeding. In this connection the question also suggested itself whether it would not be well always to put in a drainage-tube for the first twenty-four hours.

In answering the Chairman's question, DR. WYLIE related another case in which at laparotomy he found a great number of fibroids, dense and extensive adhesions, due, he felt sure, to old abscess. He managed to discover the tubes and ovaries in the midst of the adhesions, but was unable to find an intestinal opening which he thought, under the circumstances, must exist. Having left in a drainage-tube, as he always did where there had been extensive oozing, much serum or ascites, he had his assistant, at the close of the operation, make suction. There was sufficient blood to lead him to reopen the

abdomen, and he found a bleeding-point in the left pedicle, where it had been pierced by the needle. He also concluded to search again for a possible intestinal opening, and found one as large as his finger pretty high up. The patient was going on to recovery, but certainly would have died had the drainage-tube not given him the indication to reopen the abdomen. He thought that in the majority of laparotomy cases so-called shock meant hemorrhage, yet real shock might occur, in a comparatively acute case where the patient was very weak, and cause death.

Gynecological Table.—Dr. Francis Foerster exhibited a gynecological table which he had devised and used for a year with much satisfaction. It was composed of iron and steel, mostly galvanized, weighed less than fifty pounds, the legs folded under, making it portable. It was also adaptable to the Trendelenburg posture.

Puerperal Phlegmasia Alba Dolens.—Dr. J. H. Fruitnight read a paper with this title. Uncertainty and change, he said, had been characteristic of views on the pathology of the disease. It was most probable that the affection was produced by an occlusion of some of the veins of the lower extremity, and the chief factor in the causation was thrombosis of the venous, occasionally of the lymphatic, system. This would explain the swelling, pain, œdema, and mode of resolution. The frequency of the disease in the puerperal state was not great. The author had seen only four cases in a practice of seventeen years. The disease usually made its appearance one to four weeks after delivery, although thrombi might begin to form during pregnancy. The tumefaction sometimes became chronic, and even simulated elephantiasis. It might lead to suppuration. Having described the symptoms more in detail, the author went on to speak of treatment. The limb should be elevated and rendered immobile. To facilitate softening, use ointments, etc., keep the limb warm by wrapping up in flannel or cotton; if vesicles formed, puncture. Various agents had been lauded for relief of pain. When this had subsided, apply an elastic bandage, and subsequently an elastic stocking should be worn a long time. The patient should not rise too soon, or make unusual exertion, lest a thrombus be detached and cause sudden death; she should not stand too long on the affected limb, as it was prone to lose sensibility for a time.

Milk-leg Following Operations.—Dr. Wylie had had two cases apparently of milk-leg following operations. In one case the affection, almost typical in form, followed curetting for uterine fibroid, the cavity of the uterus being eight or ten inches in depth. In the other case, laparotomy had been performed. In a third case, seen last winter in consultation with a number of other gentlemen, the patient had the swelling and other symptoms in the leg follow supposed pelvic cellulitis, with chills and fever, commencing a week after delivery. Dr. Wylie thought it well to cut down into the pelvis, although nothing could be made out but a thickness in the line of Poupart's ligament. After going down deeply, he came upon, not pus, but a thick, grumous material which was let out. In the end the patient recovered, but he could not say whether it was because of the operation or in spite of it. At any rate, where there were indications for it, one should operate.

Dr A. H. Buckmaster had seen two cases of puerperal phlegmasia alba dolens in a private practice. He had also seen phlegmasia of the left leg follow, within twenty four hours, an injection of creoline into the uterine cavity which an unskilled nurse had accidentally made when told to inject the vagina. Perhaps it was a mere coincidence.

A Septic Disease.—Dr. R. A. Murray thought there were very few cases of this disease compared with the number seen formerly, when little attention was paid to asepsis. A number of years ago many cases were seen at Bellevue, in some the cause evidently being due to retained portion of placenta, use of dirty instruments, bad air of the wards. Inflammation might be found in the tubes, sometimes it had extended through the lymphatics instead of through the veins. If it extended through the lymphatics there was apt to be involvement of the broad ligaments. The crural lymphatics were affected only where there was involvement of the external genitals. The disease was due to sepsis, and this was the more apparent since in the Maternity Hospital it had been unknown after the days of antiseptic or aseptic management. He recognized two classes of cases, namely, those in which the lymphatics were involved and there was a solid œdema which required a long time to get well, and those of femoral phlebitis, with puffy œdema which could be relieved by raising the limb, and which usually disappeared altogether unless there were a varicose condition produced by occlusion of the vein. He thought if patients with subinvolution were not allowed to get up there would be less milk-leg. He had seen several cases with an analogous condition following typhoid fever. Usually in both cases, it seemed, the left leg was affected.

Septic and Benign Forms.—Dr. Schmidt thought the term phlegmasia alba dolens had not been well chosen. There were, in his opinion, two classes of cases, the septic and the simple or benign. The latter seemed to be due to thrombosis, the result of weakened heart action.

Dr. Ralph Waldo said, in corroboration of the view just expressed by Dr. Schmidt, that he had seen one case of inflammation of the veins due to a weakened condition of the heart brought on by pneumonia.

The Chairman said that one of the strongest arguments in favor of the view that milk leg was due to sepsis was the fact that we saw so few cases since the days of asepsis. He could recall no case at the Maternity Hospital, and in private practice only one, and there it was due to sepsis. Whether the phlegmasia was due to the effect of the septic matter on the heart, leading to slow heart beat, was a secondary question. He asked Dr. Buckmaster whether in his case the creoline injections were made on account of sepsis.

Dr. Buckmaster replied that the injections had been directed to be vaginal, not for sepsis, but because there was a cervical laceration.

Intestinal Obstruction following Operation for Stenosis of the Cervix.—Dr. F. Spencer Halsey read the paper, which will appear in the Medical Record.

The Diagnosis Doubted.—Dr. Wylie thought that to cut the internal os with a bistoury was a more dangerous operation than laparotomy. He believed that in this case there was sepsis; probably an abscess formed, that the abscess caused more or less obstruction by pressure, which was relieved when the abscess broke, and perhaps recurred when it refilled. He did not think a band would have given way.

Drs. Murray, Locke, and Grandin also thought there was lack of proof that the obstruction had been due to adhesive bands which on giving way afforded relief. Dr. Grandin suggested long continued fecal accumulation before the operation, but Dr. Halsey seemed to think it a sufficient reply to this suggestion that the patient had not previously been constipated, and had a free passage the morning before the operation.

SECTION IN SURGERY.

Monday, November 16, 1891.

Dr. William T. Bull, Chairman.

Tubercular Osteitis of the Knee.—Dr. V. P. Gibney showed four cases illustrating final results in the surgical treatment of tubercular osteitis of the knee, operated upon at the Hospital for the Ruptured and Crippled. All the patients showed a restoration of power, sufficient to give a useful limb, enabling the subjects to be self-sustaining in different occupations, though there was a shortening of from three to five inches in the affected limb subsequent to operation, and various forms of or-

thopædic apparatus were required to overcome the disability from this shortening.

Transplantation of Bone for Ununited Fracture of the Tibia.—Dr. B. F. Curtis exhibited a patient illustrating an operation for transplantation of bone for ununited fracture of the tibia. The patient, a man, thirty-three years of age, had been caught last January in the machinery of a planing-mill and his leg thrown against a pulley and broken. Both the tibia and fibula were involved, the fracture having been a compound one, the fragments protruding more than an inch. The femur had been broken at the same time low down near the head of tibia. Under ordinary measures the fracture behaved badly, necrosis occurred in the tibia, about one and one-half inch of the bone was destroyed, it refused to unite, and a gap was left of about an inch. He was admitted to St. Luke's in June. The left lower extremity measured upon admission $33\frac{3}{5}$ inches; the right, $35\frac{3}{4}$ inches.

June 4th Dr. Curtis cut down on the tibia and found that the ordinary operation of cutting away the ends of the fractured extremities and uniting or approximating them with wire sutures would give so much shortening in this case as to result in great deformity. He therefore had cut down on the fibula and cutting out a segment of this bone he pushed it with his fingers, without exposing it to the air, through the soft tissues and into the gap in the tibia. Firm union had subsequently taken place and the man could bear his entire weight upon the fractured limb two months after operation. He used a crutch still, as he had only been walking about for some two weeks.

Trephining for Relief of Paralysis and Convulsions from Cerebral Hemorrhage.—Dr. A. J. McCosh exhibited a boy aged seven upon whom he had done successfully the operation of trephining for the relief of recent paralysis and convulsions. In August last the boy fell down stairs and was found lying in a semi-stupor at the foot of the stairs shortly after. He remained semi-comatose for twenty-four hours after he was brought to the hospital the next day, only rousing up when violently shaken or otherwise so disturbed. There was no sign of injury to the scalp and no paralysis of motion or sensation upon his examination at the time of admission. On the third day the stupor lessened and signs of cerebral irritation appeared. The legs were drawn up and the arms flexed, the boy only slightly noticing his surroundings. On this day (third) it was noticed that he could not speak intelligently, and that he was quite irritable. The fifth day he was less irritable in temper and spoke. The next day his mind was clearer, but movements of the left upper extremity were sluggish. On the seventh day this impairment of motion was more marked, and there was also loss of power in the leg and face of the same side, with twitchings of the muscles. During the latter half of this day the boy had repeated convulsions, distinctly localizing in significance the movements, beginning in the arm, which was paretic, and thence extending. The eighth day he was found to be affected with a complete left hemiplegia. The diagnosis was made of pressure from clot over the right motor area for the arm, face, and leg of the opposite side, and it was decided to trephine at once. On lifting up the scalp and exposing the skull the bone was seen to be perfectly healthy. The fissure of Rolando having been previously marked out a button of bone was removed over the præ-central convolutions in front of the Rolandic fissure. On exposing the dura mater it appeared normal for the most part, but at the posterior extremity of the trephine opening the edge of a blood-clot was seen. With the rongeur forceps more bone was removed, exposing a large circular clot which covered the mid-portion of the Rolandic fissure and the adjacent præ- and post-central convolutions. The clot was carefully washed away and underneath was found a tear about an inch in length in the dura, due to a spicule of bone, which was removed. The underlying brain-tissue was found to be a grumous-looking, broken down mass. This was carefully washed away, the dura wound closed, and the scalp flap brought over the wound and closed with provision for drainage, no bone being replaced. The boy had made violent resistance to the anæsthetic (chloroform) with his right arm and leg when undergoing the operation at first, but did not move the left side of his body. On coming out of the anæsthesia he moved the left arm also, and kept up this movement for half an hour, after which the left side remained paralyzed as before for twenty-four hours. The paralysis then began to improve, and the boy now has equal strength on the two sides. He has not had any convulsions since the operation. The convalescence was uneventful, the wound of scalp healing readily.

Hysterectomy for the Cure of Prolapsus Uteri.—Dr. McCosh, in the absence of the patient, showed a photographic representation of a prolapsus uteri upon which he had recently operated by hysterectomy. The patient was a washerwoman and had suffered from prolapsus for some time, though, until shortly before operation, she had been able to continue her work. When admitted to the hospital the prolapsed mass protruded outside the vulva as a tumor, the size of a Derby hat. Attempts to replace the mass were utterly futile, even after three weeks' rest in bed and the most assiduous employment of all ordinary measures to reduce it in size. The mass consisted of the uterus, twice its natural size, with elongated cervix, the bladder on the anterior surface of uterus, and the thickened cervico-vaginal wall. The operation of hysterectomy was decided upon and done with very gratifying results, the patient now being able to attend to her household duties and ordinary work without discomfort. Hysterectomy in such cases, according to the experience of the speaker in this and some three or four similar cases, was a most tedious and difficult procedure. This was due to several factors, among others, the attachment of the bladder to the uterus, requiring great care in its removal, and also on account of the very large bleeding surface left after operating. The elongation of the cervix in such cases, being, as he had observed it, from three to four inches, with its attachment of vaginal mucous membrane requiring separation, was another tedious factor.

Skin grafting by Thiersch's Method.—Dr. C. A. Powers exhibited to the Society a middle-aged woman from whose nose he removed a papillomatous tumor about as large as the first phalanx of the index-finger. The exceedingly rich vascular supply of the tumor had necessitated the use or numerous cat-gut ligatures to control the hemorrhage. This he had found would be likely to interfere with the success of grafting with a single piece of skin, so desirable from an anæsthetic or cosmetic standpoint, and he had therefore used three skin-grafts instead of one. The result, as shown in this patient, afforded a very happy illustration of the value of skin-grafting by Thiersch's method.

The Chairman, Dr. William T. Bull, in connection with the subject illustrated in Dr. Powers's patient, and as *apropos* to the reference made by the latter to the cosmetic advantages of a single graft, showed to the Society a photograph of a patient upon whom he had been able to successfully carry out this procedure to remedy the deformity resulting from a deep "pit," left by an operation upon the patient's face.

In the general discussion following the exhibition of cases, Dr. Dawbarn asked Dr. McCosh, in connection with the case of trephining done by the latter, if pus was found upon exposing the brain, since, if such had been the case, an attempt at bone-grafting would have resulted in failure. He was reminded by the history of Dr. McCosh's case of one he had himself operated upon just a year ago. A man had been struck on the head in a political altercation and several days afterward, when seen by Dr. Dawbarn, he was in a semi-stupor, with elevated

temperature (101° F.) and hemiplegia. There were two wounds of the head, on opposite sides; one of them corresponding exactly to the motor area, affection of which was supposed to be responsible for the man's hemiplegia of the opposite side. The patient was taken to the Polyclinic Hospital. Dr. L. C. Gray saw him in consultation. Dr. Gray agreed with the speaker that there was pressure, probably from hemorrhagic clot, over the motor area corresponding to the wound of scalp with beginning inflammatory action as evidenced by the febrile reaction. The skull was trephined and the dura mater exposed, bulging through the opening, but looking perfectly healthy. The brain was explored in every direction, but nothing found, although the exploratory puncture reached the lateral ventricle several times, as shown in an escape of cerebro-spinal fluid. The bulging of the brain encouraged the idea that something would be found and another trephine opening was made on the same side, a little farther back, the first having corresponded to the wound in the scalp. The second opening revealed nothing to account for the patient's symptoms, the man dying six hours after operation. At the autopsy nothing abnormal was found in the brain on the side opposite the paralysis, but on the other side (the same upon which the paralysis existed) there was present a very large blood-clot, pressing upon the motor centres. In answer to a note written to Dr. Gray, stating the facts of the autopsy, he had received a note from him in which Dr. Gray expressed the belief that the only explanation of the case was that there was no decussation in the pyramidal tracts of the pons-medulla in this man's case, a condition he had only met with once or twice before. Dr. Gray asked for the brain and pons-medulla removed at the autopsy, which he examined after hardening and staining, finding, as had been anticipated, that there was no decussation in this case.

Dr. Dawbarn drew the lesson from his experience in this case that hereafter he would follow his physiology in such cases in a first operation, but failing to find anything, he should do his second trephining on the opposite side.

Dr. Joseph D. Bryant had recently had a case similar to Dr. McCosh, and was also reminded of two cases like Dr. Dawbarn's which had come within his knowledge. In one case, his own, the lesion had been found on the same side as the paralysis, the patient having been one he had seen in the service of Dr. Janeway, who had called upon him to operate, the patient dying, however, before the operation was done. Another case similar to Dr. Dawbarn's had been reported to him in a private letter from a former student, who had asked him to explain the contradiction of teaching with his case, which letter Dr. Bryant had not yet answered.

Dr. Manly described a recent case of trephining which he had done, the results being quite satisfactory, except that a hernia cerebri had resulted. He desired to hear an expression of opinion from those present as to the best plan of treatment for this condition so as to bring about a rapid cure.

Cases Illustrating Some Difficulties in the Use of the Cystoscope.—The first paper of the evening, entitled as above, was read by Dr. L. B. Bangs. The writer had no special preference between the two instruments manufactured by Mitze and Leiter. The recent French cystoscope he considered as cumbersome and unnecessarily complex. Practice was required before efficiency could be attained in the use of any cystoscope, and even with the most skilled practice there were several difficulties to be encountered which, in some instances, rendered the instrument of little practical value. He described the case of a patient, illustrative of one of these difficulties, because of free hemorrhage in the bladder so obscuring the field as to make a cystoscopic diagnosis of its cause impossible. Bimanual examination and the sound disclosed a growth, presumably papillomatous, which was operated upon by the supra pubic method, and the diagnosis confirmed, with relief and cure for the patient. Another difficulty he had encountered was the presence of optical illusions, giving rise to a false diagnosis. By too close an approximation of the beak of the instrument to the vesical wall, one sometimes got a false visual impression, and a fold of the bladder might be readily mistaken for a neoplasm. Exactly such an experience had befallen the writer. He had opened the bladder to find the tumor not present when he thought he had seen it, though other small gray or whitish patches, which had been observed also, were found to be malignant and removed with relief to the patient. Dr. E. Harry Fenwick had called attention to this liability to error in the use of the instrument, and he could confirm it. One observation he thought was never sufficient for a diagnosis with the cystoscope, because of variations in size, shape, etc., in different bladders.

In certain cases in elderly men with enlarged prostates and a tortuous urethra, the use of the cystoscope was attended with difficulty, and at times was impossible. Cocaine he had not found of any advantage in these or other cases. Notwithstanding these difficulties, the writer was a firm advocate of the use of the cystoscope as a means of diagnosis, and considered it of the greatest value.

Dr. W. K. Otis, in the discussion which followed, remarked that hemorrhage, if sufficient to obstruct the view with the cystoscope, could not be from the kidney, as hemorrhage from the kidney was slow through the ureters, and it was easy to tell by the discharge through the ureter which kidney was affected. One cause of difficulty and error in the use of the cystoscope was to be found in the spherical aberration of the instrument itself, and this was especially true of the French instrument, through which a penny looks like a globe. He was now trying to devise one which would give a flat field. One advantage of the French instrument existed in one's ability to determine the exact size of a tumor or growth in the bladder. This could be done by means of the scale on the telescope and by gauging the focus.

Dr. Willy Meyer thought that sufficient importance had not been laid upon the fact that, in every case, as much as five ounces of water should be used to distend the bladder. If this could not be done at first, he stretched the bladder by repeated injections, using a hand syringe and not a fountain. In cases of hemorrhage, wait, if possible, for hemorrhage to cease. The cystoscope could not be used when the urethra would not pass a No. 23 sound. In the case of Dr. Bangs's patient, which he had seen with him, in which the cystoscope gave a false visual impression, the bladder had not been sufficiently distended, as only four ounces of water had been injected.

The Chairman, Dr. Bull, asked Dr. Bangs if he had ever known the use of the cystoscope to be followed by any dangerous or injurious consequences to the patient.

Dr. Bangs, in reply, stated that he had never personally seen any bad effects, but recently, while in Washington, he had heard of a case in which the bladder-wall was burnt through the use of the cystoscope. He could readily see how this was possible, since, in experiments upon the phantom bladder, he had found that the finger placed near the beak of the instrument, and kept there for a time, became uncomfortably warm, in spite of the surrounding volume of water.

Considerations upon Medical Hemorrhage Surgically Treated.—Dr. R. H. M. Dawbarn read a paper with this title (see p. 1).

In the discussion which followed Dr. Van Arsdale stated that his experience had been the opposite to that of the writer of the paper, as regards the value of saline solutions. They had proven of little value, while he had seen immediate and striking benefit from the transfusion of blood. His experience with the infusion of a saline solution had been limited to only five or six cases he admitted, and he therefore felt some hesitation in advancing

any decided opinion as to the relative value of the two methods.

The Chairman, Dr. Bull, had many times proven the value of saline infusions of hot water in cases of hemorrhage, and kept on hand constantly in his operating-room the salt mixed with bicarbonate of soda in quantities proportioned for the water to be used. As regards puncture of the femoral artery, he thought it would be wise to wait until Dr. Dawbarn's experience should become more extended before adopting this measure, as there might be serious damage resulting from a puncture, no matter how small, into the walls of so important a vessel.

Dr. Dawbarn closed the discussion.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ALBUMOSURIA AND ITS SIGNIFICANCE—THE RECENT OUTBREAK OF EPIDEMIC SKIN DISEASE—THE COLLEGES OF PHYSICIANS AND SURGEONS—THE JOURNAL OF PATHOLOGY—LONDON WATER-SUPPLY—INFLUENZA—THE NEW UNIVERSITY.

London, December 5, 1891.

Medical terminology is apparently endless and is ever-changing, to the no small bewilderment of practitioners who get a little behind the times in their acquaintance with current medical literature. We are, it seems, no longer to speak of peptonuria but of albumosuria. A paper on this subject, by Drs. Lee Dickinson and W. K. Fyffe, was read before the Clinical Society last week, in which an account was given of twenty cases of pneumonia and allied conditions in which the urine contained albumose. The method employed to examine the urine was to first remove from it such proteid as was coagulable by heat, and then to treat with nitric acid and the biuret test. To apply the latter, a twenty per cent. solution of caustic potash or soda containing a little sulphate of copper was employed; the urine was floated upon the surface of this dense solution and a positive result was indicated by the appearance of a pink color at the junction of the two fluids. In no case was true peptone found, but whenever the biuret reaction was obtained it was found to be due to albumose, which could be precipitated by ammonium sulphate. The albumoses met with were proto-albumose and dextre-albumose, and sometimes occurred in large quantity (more than one per cent. when the urine was more copious than natural). Judging from experiments on animals, it seemed possible that the diarrhœa from which many of the patients suffered might have been due to the passage of albumose through the blood. Although their cases were characterized by their high mortality and their serious sequelæ (apart from empyema), the authors thought it probable that, other things being equal, albumosuria was a favorable sign in severe pneumonia and other cases, for this sign was absent throughout in some most virulent and fatal cases with extensive hepatization of lung. The origin of albumose was pus, or at least inflammatory exudation, especially that of pneumonia, and it was likely that it was formed by the agency of micro-organisms.

The recent remarkable outbreak of epidemic eczema at the Paddington and other metropolitan infirmaries formed the subject of discussion at the last meeting of the Medical Society of London. Dr. Saviel, medical superintendent of the Paddington Infirmary, opened the discussion by giving an account of the disease as he had seen it. Out of 846 patients 163 were attacked (89 males, 74 females). The disorder was attended by a certain amount of constitutional disturbance and ran a more or less definite course of seven or eight weeks. The skin lesion commenced sometimes as a papular or papulo-erythematous rash, sometimes as raised maculæ, and occasionally as rings. In all cases, however, the eruption became confluent in from three to eight days, and a crimson, irregularly indurated surface resulted which was continually shedding its cuticle in scales or flakes of various sizes. In a large proportion of the cases vesicles formed, which burst, giving rise to a serous exudation. One hundred cases were of the "moist" type, 45 were of the "dry" type, and 18 were "mixed." Convalescence was tardy, and 38 patients had relapses. Anorexia and prostration were the chief constitutional symptoms. The conjunctivæ were inflamed in all the severe cases, and in those where the face was involved. In half of the cases in which the urine was examined albumin was found. Twenty-eight patients died. Death sometimes resulted from collapse following on the vomiting or diarrhœa (which was present in a quarter of the cases), or more generally from asthenia; some patients died comatose, as in uræmia. Dr. Saviel connected two symptoms with a fatal issue—muscular twitching and dyspnœa without physical signs in the lungs. The cases which began as maculæ bore some resemblance to German measles, but pyrexia was absent and desquamation was extreme. The "dry" variety strikingly resembled pityriasis rubra, but differed in that it was epidemic and children were almost exempt. The liability to the eruption increased with advance in life, the average age at death being seventy-one. The only treatment which proved serviceable was the external application of germicides and the administration of stimulants.

Mr. Lunn, Medical Superintendent of the Marylebone Infirmary, said he had had 193 cases under observation, of which number 23 proved fatal, and in 10 of these death was certainly due to the skin disease. No treatment availed to check or modify the eruption, which had an average duration of six weeks.

Dr. Richards, of Hanwell Asylum, said he had met with 38 cases, apart from earlier cases which might have been overlooked, which was equal to about three per cent. of the inmates of the Asylum. None of the cases proved fatal, which might be due either to the effect of fresh country air or to the fact that his patients were in better condition physically than the aged and debilitated inmates of workhouse infirmaries.

With regard to the nature and etiology of the affection somewhat diverse views were expressed by the speakers on Monday evening, and no definite conclusion can be said to have been reached. Dr. Richards opined that it was a post-influenzal manifestation. Mr. Startin thought the eruption resembled what had been described by Dr. Croker as superficial erysipelas; he regarded it as certainly of external origin—as bacterial rather than neurotic. Dr. Stephen Mackenzie suggested the use of the term exfoliative dermatitis as describing the disease without involving any theory as to its pathology. He remarked that similar cases occurred sporadically, and he supposed that there must have been special circumstances of environment to account for its epidemicity in these instances. Dr. Radcliffe Crocker drew attention to the fact that in a large proportion of the cases the glands were enlarged as in rötheln; he was inclined to consider the malady a local one to begin with. Dr. Downes, of the Local Government Board, said he had made inquiries at a large number of provincial workhouses, but in only one did there seem to have been any excess of general eczema, and nothing at all answering to the disease as seen in London.

There are signs in the air of an approaching "split" between the Colleges of Physicians and Surgeons. A few years ago they entered into a joint arrangement to issue their diplomas only in conjunction with one another, and the so called "conjoint board" was formed. This working arrangement, however, is terminable at a year's notice, and it is quite possible that it may be thus brought to an end before very long. The first sign of a probable dissolution of partnership is the application just made to the Medical Council by the College of Physicians to have its license and membership recognized as registrable without

the possession of any distinct surgical qualification. This certainly foreshadows a disposition on the part of the College of Physicians to "paddle its own canoe." The Medical Council resolved, on the motion of Sir William Turner, that the College should be left to make good their claim in the way they might think fit, seeing that it would be contrary to the Medical Act of 1886 (which forbade the registration of "fragmentary" diplomas) for the Council to admit it. We have here the beginning of a very pretty quarrel if pursued to the bitter end. When the Conjoint Board was first formed the College of Physicians undoubtedly had the best of it, for by the arrange ment then entered into every student who took the diploma of the College of Surgeons—and nearly every student did —was bound to take the license of, and pay fees to, the College of Physicians also. It is doubtful whether the latter College has anything to gain by resuming independent action, but it is difficult to see what else it can have in view by the application to the Medical Council. The decision of the Council promises to land them in the law courts. While the matter was under discussion Mr. Bryant (the representative at the Medical Council of the College of Surgeons) remarked that the College of Physicians had undoubtedly exceeded its powers, and he was glad its irregularities were about to be put an end to. Coming from such a quarter, this remark was certainly ominous of some disturbance of the harmonious relations between the two Colleges.

A new medical journal is announced to appear shortly, to be called *The Journal of Pathology*. It will record the progress of original pathological research, and contributions from many of the leading workers in that field are already promised.

The London County Council and the Corporation intend to promote jointly bills in Parliament relating to the water-supply of the metropolis. It is therefore to be hoped that we are within measurable distance of the time when a purer supply will be provided.

Influenza has reappeared in this country, but has not yet reached the metropolis.

An opposition to the proposed new Albert University for London is being organized.

THE OTHER SIDE OF THE MATERNAL-IMPRESSION QUESTION.

To the Editor of the Medical Record.

Sir: After reading some of the letters which you are now publishing in regard to maternal impressions, I am impressed with the truth that there is nothing so false as figures, nothing so deceptive as facts. It seems to me that if the reporters of these astounding phenomena were to attempt some explanation, the valuable space of the journal would be better filled than with the rehearsal of what appears to reason and common sense as ridiculous. I do not wish to doubt the veracity or powers of observation of those who have reported some of these remarkable cases of maternal impression, but I am inclined to think that they have been imposed upon by hysterical women, or that the deformity of the child was a mere coincidence, due to some direct uterine cause. The imagination is a strange faculty, and, when allowed full play in a woman who has been disappointed in the birth of a deformed child, it can easily discover comparisons and concoct absurd stories for the purposes of explanation. When we remember that the fœtal deformity in these cases is usually of a traumatic character of ovarian or uterine origin; that while the physician sees the child himself, in almost every instance he has to depend upon the word of the mother for the event which is said to have preceded and caused the deformity; that when this causative event took place, the mother has usually been so excited or shocked as to seriously modify the value of her testimony in regard to it; that after the birth of the deformed child there is an almost irresistible motive on the part of the mother to offer some explanation, however absurd to science it may appear; and, finally, that no one has yet been able to prove that the deformity occurred in the fœtus at the time of the said event (a proof which is only possible by an examination of a fœtus aborted, say, immediately after one of the usual causes given for these so-called impressions) —when we remember all this, it alone is sufficient to throw discredit upon such marvellous tales.

But what are we to think of these wonderful reports when examined in the clear light of modern science? Either that the lessons of embryology have been overlooked or never learned by those who believe them, or else that they are making sport of the intelligent part of the profession by repeating the superstitious notions of imaginative and interested women.

Do maternal impressions ever occur among the lower animals? I have never heard of such, though among some of the more timid creatures frequent opportunity has not been wanting.

Could a sitting hen give a maternal impression to one of her little chicks still unhatched in the nest? I think I see an ominous smile upon the face of the reader, and yet such a suggestion is hardly more ridiculous than that a human mother can give a maternal impression to the fœtus within her womb. After the ovum has left the Graafian follicle, its principle of development resides solely within itself, and there is no direct connection whatever between the fœtal and maternal tissues. The only interchange between the elements of the mother and child is by way of the two systems of circulation brought in approximation at the placental membranes; and practically, the child within the womb is as much beyond the maternal influence as the chick within the nest. There is a possibility of chemical influences being transmitted from the mother to the child through the blood; and it is probable that certain nervous influences are exercised in the same way, *i.e.*, through some alteration in the chemistry of the blood. This explains why the mother may transmit certain diseases to her offspring, but it will never explain why that mother, by looking at a man with a deformed nose, for instance, will cause the nose of her child to be deformed. The simple statement of the case reveals its untenability.

While the ovum is still one of the maternal cells, that is, before it has started out upon its own life-history within the Graafian follicle, a maternal impression may be conferred upon it, for it will then receive the same influence that every other cell in the whole maternal organism receives. It may be similarly influenced by the direct contact of the paternal element, the spermatozoon. These two influences, however, we speak of as heredity; but heredity is not a cause of the wonderful cases of maternal impression reported from time to time in the medical journals. Let us have done with such superstitious notions. Enough marvels of that sort are already on record for the purposes of study. Let those who desire to exploit their abilities in this department of obstetrics cease to listen to these vagaries of the feminine mind, and explain, if possible, how they propose, rationally and scientifically, to account for these so-called maternal impressions. Valuable space in our journals will thus be reserved for something more practical and instructive, and common-sense will not be offended with the periodical report of these tiresome, worn-out notions of a bygone superstition.

L. Harrison Mettler, M.D.

Chicago, December 15, 1891.

Ghostly Dentists.—A man out in Ohio who was suffering from a severe toothache and consulted a spiritist medium for relief, was told to go to bed and the relief would come. He obeyed, and upon recovering consciousness he found a blood-stained pillow and the offending molar on the sheet. He is deliberating whether it was nitrous oxide or spiritism, but is glad his tooth is out anyway.

SANITARY HORSEBACK RIDING.

To the Editor of the Medical Record.

Sir: After one has lived for even a few months in the Far West the subject of horseback exercise becomes a topic most absorbing.

The pure air and almost constant sunshine invite one to lead an out-door life. The shady mountain passes, with the constant change of superb views, from cañons to peaks, and the glimpses of the vast expanse of plains with an horizon like the ocean, tempts one to take exercise which otherwise they would probably not have strength or energy to do. Then to canter on the prairie is so fascinating that one scarcely knows when to stop. "To sleep in a tent and live on one's horse by day" is a prescription that has saved the life of an otherwise doomed mortal; but I am sorry to say that I fear that it has been greatly abused, and that rash exposure has been guilty of taking to an early grave many who otherwise would have grown well and strong.

It should be remembered that riding, even walking, one's horse gives no little exercise; it is naturally fatiguing, indeed exhausting, and one should bear in mind an axiom in the treatment of pulmonary diseases—never to fatigue, but to exercise gradually as the strength increases.

Time and again doctors have told me that patients have come to them in various stages of consumption, some, indeed, in a very debilitated and dangerons condition, buoyed by hope and armed with instructions from the home doctor "to sleep in a tent and take plenty of horseback exercise." Carrying out this advice a fatal hemorrhage would probably prove its harmfulness.

In the studies that I have made in various forms of physical exercise especially beneficial to children and delicate women, I have been impressed with the fact that the perfection of exercise was that which moderately brought into concerted action all the muscles of the body and tended to symmetrically develop the individual, and that well-sustained exercise of this character equalized the circulation, produced no congestions or strain, and stimulated arterial and venous flows. For a man horseback riding possesses all these qualities; but, strange to say, the woman is so hampered by fashion that I am more and more impressed with the fact that in a large number of cases riding with the side-saddle does far more harm than good.

I have thought this matter over carefully, and am prepared to state most emphatically that I believe the time has come when the side-saddle should be abolished. The position a woman assumes on horseback has three objections: 1st. The right leg being at an angle with the body and more or less fixed, the to-and-fro movements of the body cause more or less pressure upon the abdominal and pelvic viscera; the seat necessarily produces a slight spinal twist in the lumbar region, and should, as unfortunately is too often the case, a perfect fitting habit or a tight corset be worn, all these evils are exaggerated. 2d. The left leg, partly straightened, bears upon it the entire muscular strain; especially is this the case with the upper thigh muscles, whether or not the stirrup be used; and the pressure exerted against the pommel must necessarily retard the circulation in the venous and arterial trunks; this strain, which is always more or less on the left side, certainly must affect the pelvic viscera, especially the left ovary, should it have any tendency to prolapse or congestion—a frequent condition. 3d. I believe that this method of riding is unsafe, as it by no means gives a woman the control of her horse in cases of danger that she should have.

However straight a woman may try to hold herself in the position she assumes on a horse, she will gradually fall into the habit of a slight lumbar curvature to the left, and it stands to reason that, for one who rides a great deal, a want of symmetry in development on both sides will be sooner or later noticeable. I believe this is obviated to a certain extent in England by the movable pommel, the young rider being obliged to ride on one side one day and on the next the other.

I am surprised that those who have seen much of the diseases of women have not taken a more positive stand in this matter. There is no reason whatever, except the arbitrary dictates of fashion, why a saddle could not be so constructed that a girl could ride with equal comfort and grace as can her brother; moreover, she would get far better control of her horse, and there would be very much less danger of ovarian and uterine prolapses, bladder disturbances, lateral spinal curvatures, etc. Those who have had courage enough to try this innovation have assured me that the difference in comfort was remarkable.

In order to secure the advantages of riding astride, a woman should, I think, have a saddle constructed in a manner different from that used by men. This saddle should combine healthfulness, safety, and comfort. Healthfulness would require an erect symmetrical posture of the rider, freedom from angles that would interfere with perfect circulation and would prevent any strain or pressure on the pelvic organ. Safety would give a firm seat, sure control of the horse, and an easier mount than can now be accomplished. Comfort would come from freedom from restriction and an easy seat.

My idea would be to make a saddle based upon the following plan: The pommel to be somewhat of the Whitman type, but with a twenty-inch seat, a flat ladies' cantle with rolled edges; this would give sufficient length and would expand into a broad, comfortable seat. The rider, then, instead of assuming a perpendicular position, has the legs flexed almost as much as when sitting on a comfortable chair. There should be for this purpose a stirrup shorter than that worn by men; the flaps then could be padded very much as is now done in the Kentucky saddle. I feel convinced that this form of saddle would be found to be the most useful one that could be adopted.

John M. Keating, M.D.

Colorado Springs, Col.

THE DOSE OF PARALDEHYDE.

To the Editor of the Medical Record.

Sir: In the Clinical Department of the Record to-day, under the caption of "A Large Dose of Paraldehyde," Dr. J. Noer calls attention to a patient of his, "on the verge of delirium tremens," having taken two and one-half drachms in one dose, instead of fifteen minims every half-hour, which he had prescribed, and concludes by stating that "the maximum dose of paraldehyde is four grammes, or one drachm."

The doctor is mistaken. The maximum dose of paraldehyde is *not* one drachm. When conditions favor it may be given in doses of six, eight, or more grammes, without fear of ill effect.

Obersteiner, the eminent Austrian alienist, in the recent report of his private asylum, near Vienna, a copy of which was kindly sent to me by the author, and is now being translated by my assistant, Dr. Herbert Adams, says: "Paraldehyde, soon after its discovery, took a place next to chloral as a hypnotic. It can be used in all cases where it would not be prudent to use chloral. It is a valuable and scarcely replaceable medicine among our therapeutic agents. We never give above the medium dose of six grammes, but four to six grammes are often insufficient, and to obtain satisfactory results one must use much larger doses. It is possible to take twenty, yes, even forty grammes, daily."

Our usual dose of paraldehyde is two drachms. We have used it for years, prize it highly, and have never noted ill effect.

We certainly should not expect a man "on the verge of delirium tremens" to sleep by taking fifteen-minim doses every half-hour for five hours. Better, by far, if clearly called for, give two or three drachms at once, and

then smaller doses, if needed. Some of our best soporifics—chloral, cannabis, bromide of sodium, etc.—often fail because of too timid dosing.

J. B. Mattison, M.D.

Brooklyn Home for Habitues, Brooklyn, December 19, 1891.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 26, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	4
Scarlet fever	196	23
Cerebro-spinal meningitis	1	1
Measles	83	2
Diphtheria	152	46
Small-pox	0	0
Varicella	8	0
Pertussis	2	4
Erysipelas	2	0
Mumps	0	0
Rötheln	0	0

Laryngeal Diphtheria, according to Rosenberry, should be treated with the following:

℞. Ol. eucalypti,
Ol. terebinth ..... āā ℥j.
Ol. vaselini ..... ℥vj.
S.: Use in a steam atomizer every half-hour.

A Salivary Calculus.—Dr. George H. Pierce, of Danbury, Conn., reports the removal of a salivary calculus, which had been forming for twenty-seven years. A swelling was first noticed beneath the tongue, on the right side, of the gentleman from whose mouth the stone was removed, in 1864, at the time of his leaving the army. It had gradually increased in size until a tumor had formed which reached nearly to the level of the teeth, and was interfering with the speech. When I was consulted in November, the calculus had ulcerated through its enclosure at the top, which caused the gentleman some fear lest it might be a cancer. Upon inspection I thought at first of nothing but a simple ulcer, and proceeded to cauterize it with the solid stick of nitrate of silver. As I touched the surface I struck something hard like a stone, and upon further investigation estimated that it was about the size of a large marble. I made an incision along the upper margin of the tissues enclosing the stone, and extracted it without difficulty, by catching it with pincers. It lay loose in the tissues. Instead of being spherical the stone was oblong in shape, being 1⅜ inch long in its greater axis, and ½ inch in its lesser. It weighed sixty grains and was quite compact. The cavity healed in a day or two.

"Le Languedoc Médical," is the title of a new medical journal established in Toulouse under the editorial direction of Drs. J. C. Artigalas and A. Rémond. The first number contains articles on "Tracheo-bronchial Adenopathy of Hereditary Syphilitic Origin," by Dr. Artigalas, and on "Nervous Polyuria," by Dr. Rémond, in addition to the ordinary society reports, etc.

Leprosy in Bokhara.—It is said that leprosy prevails to a considerable extent in Bokhara, and indeed that the focus of the disease for the whole of Central Asia is found in a certain quarter of the city of Bokhara. Since the country has come under Russian influences the Emir has been prevailed upon to take steps for the isolation of the lepers in his dominions, as well as to establish a special hospital for them where they may be treated by European experts. At present they roam about wherever they will without any restraint whatever.

A Spanish Edition of "La Semaine Médicale" has been decided upon, to appear simultaneously with the original.

Physicians Wanted for Jewish Colonies.—The Jewish Colonization Association advertises in the German medical journals for physicians for their Russian Jewish Colonies in South America. Applicants must speak German (those who can also speak the Jargon will be preferred), have had hospital experience, and must sign a contract for three years' service. Further information can be obtained from the director of the Association in Paris, Dr. Sonnenfeld, 36 Rue de Bellechasse, to whom also applications for appointment should be directed.

As Their Tailors See Them.—A writer in a French contemporary says that a comparison of some fifty tailors' patterns of thirty years ago with an equal number of those used to-day shows that eighty per cent. of the young men of the present time are hollow-chested and round-shouldered; the shoulders are sloping, the neck projects forward, and the hips are prominent. We fear the writer of the article is an old fogy who sees no good in this degenerate *fin de siècle*, or else the young men in France are very inferior to the youth in this country.

A Medical Journal in Guatemala.—The turbulent little country of Guatemala has now a medical journal called the *Gaceta Médica Quezalteca*, which is published in Quezaltenango twice a month.

Antipyrin Asthenopia.—A writer in *The Lancet* relates a case of impairment of vision for distant objects coming on rather suddenly in a man, aged thirty-two, who had been using antipyrin pretty steadily for several months. The writer is inclined to put the blame for the impaired vision upon the antipyrin, and asks if any others have seen a similar effect from the use of the drug for long periods.

An International Congress for the Study of Prostitution.—The Paris Municipal Council is about to organize an international congress for the study of questions relative to prostitution and the spread of venereal diseases. It is proposed to hold the congress in Paris in 1893. Not only medical authorities, but jurists, hygienists, and political and social economists will be asked to take part in it.

To Relieve the Surplus Nursing Energy.—The Wesleyan Church in England is about to establish a hospital of its own, the alleged reason for doing so being to give the female members of the sect an opportunity to nurse the sick. They say that they are now denied the privilege in the hospitals under the religious control of the Established Church. That's a grand idea, and we hope the Wesleyan doctors also approve.

The University of Lemberg is about to be blessed with a medical faculty, the Emperor of Austria having approved of the proposal to establish one. It is thought it will be ready and in good working order by the autumn of 1894. Well, we should hope so! Oklahoma will have two or three medical colleges in full blast by that time.

A Folk-lore Remedy for Whooping-Cough.—Dr. E. V. Hunt writes to *The Lancet* that while staying at Folkestone recently he got into conversation on whooping-cough, one day, with a bath chairman. The man said that he knew of a certain cure for this complaint, which was to cut some hair from the nape of the child's neck, put the hair between two pieces of bread and butter, and make a dog eat it. He said the dog caught the whooping-cough, and probably died of it, but the child recovered. On rather strong doubts on the point being expressed by the listener, he asserted it was positively true, for it had proved a cure in the case of his own children.

Photophobia, with dilatation of the pupil, is said by Huguin to be an early diagnostic sign in pertussis before the whooping stage comes on.

CURED PHTHISIS.

1. Photo-micrograph. Tubercular area enclosed by new connective tissue.
2. Photo-micrograph. Contracted cavity surrounded by fibrous tissue.
3. Healed cavity.
4. Upper lobe replaced by fibrous tissue.
5. Fibrous nodule at apex.

A STUDY OF THE PROCESSES WHICH RESULT IN THE ARREST OR CURE OF PHTHISIS.[1]

BY HENRY P. LOOMIS, M.D.,

NEW YORK.

I HAVE endeavored, in a series of observations extending over the past two years, and by the aid of abundant material which has come to me during my service as Curator at Bellevue Hospital, to obtain some explanation of the following anatomical changes which form a part of the morbid anatomy of pulmonary tuberculosis:

1. In what proportion of cases met with on the autopsy table are found the evidences of cured pulmonary tuberculosis?

2. What are the gross and microscopical appearances presented by the lungs in these cases, and by what histological changes was the cure effected?

3. In the healed lungs, are tubercle bacilli still present?

4. How often are the evidences of localized or general adhesive pleurisy found, and what effect have such pleuritic changes had on the pulmonary structure?

Anyone who has the opportunity of making a large number of autopsies soon becomes impressed with two facts: First, it is the exception to find perfectly normal lungs, or lungs which are not more or less firmly bound to the chest-wall by old pleuritic adhesions, either localized or general. These adhesions are sometimes so firm and dense that the lungs can only be removed with the costal pleura attached. Secondly, the number of cases where the lungs must at some time have been the seat of an active and often extensive tuberculosis, yet at the time of death all traces of active processes have disappeared and the destroyed pulmonary parenchyma been replaced by fibrous tissue.

This tissue generally shows itself at the apex of otherwise normal lungs, as firm, dense, circumscribed masses, which vary in size from a half to two inches in diameter, and have in their centre cheesy or calcareous concretions. Sometimes a small and completely encysted cavity is met with in otherwise healthy lungs. For a long time, I have been convinced that the evidences of a cured phthisis are present, much more frequently than is generally supposed, in the lungs of those who present no signs of the existence of phthisical processes at the time of death. This impression has been confirmed by a study of the carefully recorded reports of 1,146 post-mortem examinations made at the dead house of Bellevue Hospital. Those reports which were incomplete have not been included in this study. Of these 1,146 autopsies, 383 were made on persons who died either from tuberculosis, or showed in their organs an active or chronic tubercular process. This left 763 autopsies made on non-tubercular subjects; of these, 276, or thirty-six per cent., showed lungs which were bound by organized adhesions, either general or local, to the chest-wall. In all of these 276 cases the lungs were free from disease, except the pleuritic changes which, in most instances, interfered materially with the perfect expansion of the lungs, as the study of microscopical sections made from the underlying pulmonary tissue clearly demonstrated. Of the 763 persons dying of a non-tubercular disease, 71, or over nine per cent., presented in their lungs changes which I regard as characteristic of healed pulmonary tuberculosis. Many writers on phthisis give the percentage of cases of cured phthisis as much lower. For instance, Dr. Williams, of London, out of 1,000 cases in private practice, states a cure was effected in 4.6 per cent.; Dr. Austin Flint, in 640 cases, says a recovery took place in 44, or 6.5 per cent.

These conclusions were reached from physical examinations, and not from post-mortem appearances. When we study tuberculosis from a pathological standpoint, we look more hopefully on the disease as amenable to cure. Vibert,[1] from the register of the necropsies made at the Paris morgue, found in 17 out of 131 persons dying from violence or sudden death the evidences of pulmonary tuberculosis which had been cured. This is a little over twelve per cent., and shows a higher rate of cured phthisis than that obtained by me. Joseph Coats, of Glasgow, reports that out of 103 persons dying of a non-tubercular disease, 20 showed in their lungs the evidences of healed phthisis; this is a little over nineteen per cent. The report of the Middlesex Hospital, compiled by Dr. Fowler, gives the arrest and cure of pulmonary tuberculosis in 177 cases out of 1,943 necropsies which were made by him; this is about nine per cent. Dr. Sidney Martin reported before the British Medical Association that in 445 consecutive post-mortem examinations he had found 42 cases of healed tuberculosis in the lungs, or 9.4 per cent. These 42 persons died of a non-tubercular disease; 7 of them of cancer. This relation between cancer and healed tuberculosis has been observed and commented on by all investigators in this field. As these percentages are much higher than those given by clinical observers it is evident that recovery from phthisis is more frequent than generally supposed. The class of cases examined at the Bellevue dead-house came from the lower walks of life, and during life were under the worst possible hygienic conditions, and yet nine out of every hundred furnished those pulmonary lesions which are evidences of cured phthisis. The question which may naturally be asked is, what are the lesions which are evidence of cured phthisis, and how can one say the disease is cured from the appearances which are found?

If by the term "cured phthisis" is meant a complete restoration of the affected portion of the lungs to a normal condition, we can say that it never occurs; but if it is meant that all pulmonary symptoms cease, that the patient has good health, and that the damage to the lungs is not sufficient to prevent an adequate use of their functions, and that the tubercle bacilli, if present, are rendered inert by the connective tissue which surrounds them, and are finally destroyed, then we can say that a cure takes place in very many cases—a number much larger than is generally supposed.

It is impossible to understand how recovery from primary or secondary areas of tubercular infiltration in the lungs can take place by absorption of the tubercular material, and the restoration of the lungs to a perfectly normal condition. If, then, every tuberculosis, although cured, leaves its permanent stamp on the tissues, what are the steps by which an exceedingly destructive process becomes arrested and cured?

In describing these changes, I will speak, 1, of their situation; 2, of their gross appearance; and 3, of their microscopical appearance.

[1] Read before the Section on Practice, New York Academy of Medicine, December 15, 1891.

[1] London Lancet.

The post-mortem appearances in cases which may be regarded as cured will necessarily vary with the extent of the tuberculosis and the stage to which it had advanced before its arrest. As phthisical processes are usually confined to the apex of the lung, the changes of repair were better marked here than elsewhere, although in a few instances these changes were found in other places, especially the posterior aspect of the lower lobes, and in the lower part of the upper lobe. On the basis of their gross appearance, I shall group my cases under the following heads:

First.—*That class in which the apex of the lung is found adherent to the costal pleura, with a puckered and depressed condition of its surface.* Sixty of the seventy-one cases which form the basis of this paper showed this condition. On cutting into the lung, one or more dense fibro-cartilaginous nodules, varying in size from a cherry to a walnut, are seen beneath the depressed surface, or, if situated in the central portion of the upper lobe, are generally connected with the surface by easily recognizable dense bands of new connective tissue. In the centre of these nodules, a chalky mass is often found, sometimes soft, but generally of sandy consistency, and often studded with sharp spiculæ, as hard as bone.

Photograph 5 shows one of these nodules situated at the apex of the left lung. The puckered appearance about the nodules is due to the contraction of the newly formed connective tissue. The surface of the lung over the nodule was adherent to the costal pleura. The contents of the mass was cheesy, of a dark gray color, and contained no tubercle bacilli. In a few instances, the centre of the mass appears dense and cartilaginous, and the nodule presents the appearance of a solid body. Surrounding these nodules are laminated fibrous deposits, traversed by contracted, obliterated, or dilated bronchi. The nodules were generally circumscribed, round, or elongated, and surrounded by pulmonary tissue which appeared normal, although it was often found on examination to be only in part permeable to air, or to be the seat of well-marked emphysema.

In a few cases, the indurated portions of the lungs were not nodular, but diffuse and more extensive, and these were situated, not in the central portions of the lung, but in connection with the pleura. They consisted of dark gray fibrous tissue, dense, tough, and often very hard, resembling cartilage, and contained no caseous residues, although generally some were scattered throughout the tissue, and appeared to be derived principally from altered bronchial secretions.

Photograph 4 shows the substance of the upper lobe of the right lung entirely replaced by new fibrous tissue. The pleura is greatly thickened. The rest of the right and all of the left lung were perfectly normal.

Often all trace of alveoli had disappeared. Connected with the thickened pleura are septa running through the lungs, composed of a condensed cellular substance intermingled with fibrous tissue. These septa from their whiteness form striking contrasts with the rest of the lung.

Photograph 3 shows a healed cavity in an otherwise perfectly normal lung. The wall of the cavity was nearly a quarter of an inch in thickness, and composed of dense, fibrous tissue. The cavity was empty. This is the best illustration of a healed cavity that I have ever seen. The specimen belongs to Dr. T. M. Prudden, who kindly loaned it to me.

Second.—*One of the most positive evidences that phthisis which has gone on to the formation of cavities can be recovered from, is the aspect presented by healed cavities.* Six of my cases showed this condition, and divided themselves into two forms:

1. Where the cavity was empty and communicated with a bronchus. I have met with but two of these cases and both of them were found in the central portion of the lung. The cavities are closed on all sides and lined with a thick, dense fibrous or fibro-cartilaginous membrane, sometimes half an inch in thickness. This forms an internal cicatrix analogous to a fistula. The cavity is kept open by adhesions of the lobe to the chest-wall. Sometimes these cavities are not empty, but partly filled with calcified tubercular material, or a fibro-cartilaginous mass due to vegetations from the wall of the cavity. The surrounding pulmonary tissue is rarely perfectly healthy, generally it is indurated, infiltrated with black pigment, and puckered by shrinking.

2. Most frequently the cavity was contracted to such an extent by the growth of fibrous tissue that it was almost obliterated and appeared as a linear cicatrix. I have often found this connective-tissue over an inch in thickness, surrounding what remained of a cavity.

Photograph 2. This is a photo-micrograph, showing the great increase of connective-tissue about a contracted and almost obliterated cavity. At the lower portion of the photograph new connective tissue could be seen forming in the alveolar walls.

The adjoining pulmonary tissue may appear normal, although, when examined, it is found to be generally the seat of emphysema, and to contain patches of interstitial pneumonia. The condensation and contraction in the pulmonary tissue causes the emphysema, and is, I believe, essentially connected with the spontaneous cure of pulmonary cavities. Sometimes calcareous concretions, like small, opaque, granular, or chalky deposits, are found in the centre of the cicatrix; these are the contents of the obliterated cavity. (In the young, the calcareous deposit takes place at the periphery, leaving a calcareous crust with a soft centre.) I found these internal cicatrices almost always accompanied by puckering of the corresponding surface of the lung, with depression of the chest-wall.

Third.—*Two cases have come under my observation where there had been a complete transformation of the whole of an upper lobe into a compact homogeneous mass of fibrous tissue, without a vestige of pulmonary substance.* Throughout the lobe were seen large numbers of dilated bronchi, many of them filled with calcareous matter. The whole lobe was impervious to air, uniformly pigmented, of a bluish slate color, and presented none of the gross appearances of a tubercular process. This was only settled by a microscopical examination, which showed giant-cells in large numbers, mingled with tubercular and fibrous tissue. The tissue was scantily supplied with blood-vessels; many of the bronchial veins were obliterated, and the bronchi closed.

Black carbonaceous deposits are apt to take place during the healing process of phthisis, in the neighborhood of (cretaceous) concretions and cicatricial tissue; they may be circumscribed or diffuse, and give the tissue a bluish-black or slaty-gray color. In all lungs showing the changes of healed phthisis at the periphery, and in most of those where the changes are confined to the central portions, one will find the two surfaces of the pleura adherent. A marked depression of the lung was observed in 54 out of 71 of my cases, the surface being hard, uneven, and presenting a crumpled appearance. These depressions depend on the loss of substance of the lung, and the consequent contraction which it has undergone.

Microscopical Appearances.—Normally, in the human lung, there are prolongations of connective tissue passing in from the pleura, and dividing the pulmonary tissue into rounded, polyhedral compartments or lobules. These lobules are in turn made up of a number of primary lobules, composed of a collection of air-sacs or alveoli. The prolongations of connective tissue from the pleura or interlobular septa, as they are called, are quite broad, and easily recognizable by the naked eye, for they are usually rendered prominent in the human lung by deposits of inhaled carbon in their lymph-channels. It is this interlobular connective tissue which plays the most important part in the healing of pulmonary tuberculosis.

An examination of microscopical sections presenting

the evidences of arrested and healed tubercular processes, has led me to the following conclusions :

All fibrous developments result in induration, but it is not easy to determine how or why the tubercular processes were arrested, or how the final result was brought about.

The indurated portions of the lungs were either in the form of nodular or diffuse masses. In this latter and rarer form, cheesy or calcareous residues were scattered throughout the fibrous tissue. At the edge of the pulmonary tissue, destroyed by the tubercular process, in many sections, new connective tissue could be seen just forming. This seemed to be derived from three sources.

1. The interlobular connective tissue had been infiltrated with round cells which were becoming changed into new connective tissue cells. In some, the interlobular septa had been increased ten-fold, and presented an effective barrier to the advance of the tubercular process.

Photograph 1. This is a photo-micrograph showing two broad bands of new connective tissue passing inward from the pleura, completely enclosing a tubercular area, and limiting the extension of the process. The bands are increased interlobular septa.

In all the sections, this interlobular increase was constant and most marked, and in a number seemed to be the primary change. The new connective tissue was highly vascularized.

2. New connective tissue forming in the alveolar walls was seen. In one section adjoining a contracted and encapsulated nodule, the walls of the alveoli presented all the stages of new connective-tissue formation—round cells elongating and becoming spindle cells ; spindle-cells changing into dense fibrous tissue ; with, finally, contraction and obliteration of the alveolus and its place taken by new connective fibrous tissue.

I am aware that by many the participation of the slight amount of connective tissue in the wall of the alveolus in the general hyperplasia is denied, but it seems to me without question that it does occur.

3. The connective tissue around the vessels and bronchi had become greatly increased. The latter were often almost obliterated by the contractions of the new connective tissue, but I was surprised to see how little the lumen of the pulmonary vessels was interfered with. This was marked in all sections, no matter how extensive the fibrous tissue. In the new tissue, areas of round-cell infiltration were seen, and in places, granules of black pigment occurred in the walls of the bronchi, which were most probably, however, secondary to the fibroid changes. In some sections adhesions of the pleura seemed to be the first step in the development of new connective tissue in the lung substance, for from these adhesions broad bands of new fibrous tissue were almost universally seen dipping deep into the lung. Fibrosis is a conservative process. The new fibrous tissue from the pleura and the interlobular septa offer a dense barrier to the advance of the tuberculosis, and the incipient softening is not attended as is usual by the continued deposition of tubercle. The new connective tissue by its contractions encapsulates the tubercular area, compresses and renders inert the cheesy masses, and limits the advance of cavities, reduces them in size, and finally causes them to cicatrize and entirely disappear.

I could find no evidence, as some claim, that the tubercle itself furnished any of this fibrosis. One fact especially impressed me, and that was the hyperæmic condition of the tissue which surrounded the tubercular areas where the new connection was forming. Throughout the fibrous tissue new capillary vessels were seen everywhere. An unobstructed circulation, and an intense hyperæmia were conditions so constantly present where recent fibroid processes were active that they seem to be essential to the cure of phthisis.

In the fibroid conditions which I have just described, fifteen lungs showing the characteristic lesions of healed phthisis were taken, and a half dozen microscopical sections were cut from each lung. These were stained for tubercle bacilli, and in none were any bacilli found. The sections presented all the microscopical appearances of a healed tubercular process, and I believe the lesions could have been caused by nothing except the tubercle bacilli. Some would have us believe that these fibroid nodules found at the apex of the lungs are not the result of a tubercular process, but that other irritants besides tubercle may cause them. The burden of proof, it seems to me, must rest with them. Ziegler, who has investigated tuberculosis from its anatomical side possibly more than any other observer, says, in his work on "Pathological Anatomy," that tuberculous lungs may recover locally, and the indurated patches not only contain no tubercle bacilli, but even present none of the special characteristics of tuberculosis.

The following are the reasons why I consider all these nodules of tubercular origin :

1. A number of cases have been reported where the patient was treated ten, fifteen, and even twenty years before death for extensive and well-marked phthisis, from which, after a number of years, they completely recovered, and finally died by accident, or from some non-tubercular disease. At the autopsy, the only pathological change found in the lungs to mark the seat of the old tuberculosis were these characteristic fibrous nodules. Laennec, Bennett, and Jaccoud all cite a number of cases of this kind.

2. It would hardly seem possible that any but a tubercular process could develop fibrous nodules so uniformly at the apex of the lungs.

3. The few nodules which were proven by my inoculation experiments to contain tubercle bacilli, and so beyond question to be tubercular, differed in no respect in gross appearance or anatomically from the other fibrous masses in which no tubercle bacilli were found.

Inoculation Experiments.—These experiments were conducted upon rabbits with the object of ascertaining whether the circumscribed fibrous nodules containing cheesy or chalky deposits, and found generally at the apex of the lungs, contained tubercle bacilli. The settlement of this point is important, for it is the only means we have of ascertaining whether phthisis is ever absolutely cured. Even a few bacilli remaining in an apparently healed area in the lungs must of necessity always be a source of danger to the individual.

The experiments were conducted in the following manner : The nodule or nodules were laid open by a sterilized knife, the contents removed by sterilized needles, and then dissolved in distilled water in an aseptic vessel. One to two cubic centimetres of this fluid were then injected, under strictly antiseptic precautions, into the right pleural cavity of a healthy rabbit, which was killed in from six to twelve weeks, after being kept under the best hygienic surroundings. A history of the cases from which the nodules were taken and a record of the autopsy on the rabbit were kept. The following is a detailed account of the experiments :

Rabbit No. 1. Inoculated in right pleural cavity with 1 c.c. of fluid obtained by dissolving the cheesy contents of a single nodule, three-eighths of an inch in diameter. The nodule was obtained from the upper portion of the apex of the right lung, which together with the left lung was perfectly normal. The subject from whom the lungs were removed, died suddenly from a rupture of an aneurism of the descending portion of the arch of the aorta. The rabbit was killed at the end of three months, and all its organs were found in a normal condition.

Rabbit No. 2. Inoculated with 1 c.c. of sterilized water in which were dissolved the cheesy contents of two yellowish-white nodules which were surrounded by radiating bands of connective tissue in such a manner as to give the lung about the mass a puckered appearance. The nodules were situated in the centre of the upper lobe of the right lung, and the cheesy centres were one-half and one-fourth of an inch in diameter respectively. The

man from whom the lungs were removed died from a blow on the head, which caused a fracture of the parietal and temporal bones, with laceration of the brain-substance. The rabbit was killed at the end of five weeks, and, with the exception of localized adhesion of the lung to the costal pleura at the point where the needle pierced the chest-wall, all the organs were normal.

Rabbit No. 3. Inoculated in the usual way with the cheesy contents of two nodules, each about half an inch in diameter, and situated at the apex of the right lung. The lungs, with all the other organs, were found in a normal condition. The man died suddenly from "Paris-green poisoning." The rabbit was killed in the fifth week after inoculation, and all its organs presented a normal appearance.

Rabbit No. 4. Inoculated with 3 c.c. of fluid obtained by dissolving in sterilized water the soft, cheesy contents of two nodules, one inch, and one-half inch in diameter, respectively. These nodules were situated at the right apex, an inch and a half from the pleura, and were surrounded by well-organized connective tissue bands. The pulmonary parenchyma for about an inch and a half around these nodules contained twenty gray translucent masses, the size of a pin's head, which looked like miliary tubercles. The smallest bronchi in this area contained pus. With these exceptions, both lungs were perfectly normal. The person from whom they were removed died of chronic Bright's disease. The inoculated rabbit was killed at the end of three months, and in both lungs were found consolidated cheesy masses, the size of a pea, which showed on microscopical examination, the structure of tubercles. The rest of the organs were normal. The contents of the nodules removed from this person, therefore contained tubercle bacilli, and a very recent eruption of miliary tubercles surrounded them, possibly favored by the weak condition of the person two months before death.

Rabbit No. 5. Inoculated with $\frac{1}{2}$ c.c. of fluid obtained from the contents of an old encapsulated nodule three-fourths of an inch in diameter, situated at the apex of the left lung. With this exception, the lungs were perfectly normal. The person died of general abdominal tuberculosis; miliary tubercles studded the omentum, and covered every portion of the small intestines. The nodule in the lung was the only old tubercular process found in the body. Dr. Biggs performed the autopsy. The rabbit, which had become very much emaciated, was killed on the thirtieth day after inoculation, and miliary tubercles were found scattered throughout both lungs. This is a very interesting case, and forcibly impresses the fact of the danger which may lurk in these apparently inert nodules.

Rabbit No. 6. The case from which this rabbit was inoculated was in Bellevue Hospital, under treatment for phthisis. At the autopsy the lungs were found perfectly normal, but there was an aneurism of the arch of the aorta which caused the phthisical symptoms. The contents of two nodules situated just beneath the pleura of the right apex, and about three-fourths of an inch in diameter, were injected into the right pleural cavity of a healthy rabbit. The rabbit was killed at the end of six weeks, and all its organs were normal.

Rabbit No. 7. Inoculated with 1 c.c. of a fluid obtained by dissolving the calcareous and cheesy contents of a single large nodule, an inch and a half in diameter, situated near the apex of the right lung. The nodule was surrounded by layers of fibrous tissue, one-fourth of an inch in diameter. The surface of the lung was puckered, and a broad band of new fibrous tissue ran from the nodule to the depressed surface. The patient died from cirrhosis of the liver. The rabbit was killed at the end of eight weeks, and, with the exception of a localized pleurisy, the lungs and all the organs were normal.

Rabbit No. 8. The patient, who died of heart disease, from whom this rabbit was inoculated, had just beneath the pleura in the upper lobe of the right lung a circumscribed fibrous nodule, three-fourths of an inch in diameter. In the substance of the lobe were a number of smaller nodules limited by concentric bands of fibrous tissue. All the nodules had cheesy centres. The contents of the large nodule with that of three of the smaller were dissolved in sterilized water, and 1 c.c. injected into the pleural cavity of a rabbit. The rabbit was killed five weeks after inoculation, and all its organs were normal.

Rabbit No. 9. Inoculated $1\frac{1}{2}$ c.c. of the fluid obtained by dissolving the scraping from the wall of a contracted cavity, one inch in diameter, situated in the centre of the right upper lobe. The cavity was surrounded by fibrous tissue, one-fourth of an inch thick; it was free from contents, and did not communicate with a bronchus. The patient died of cerebral hemorrhage. In the sixth week the rabbit was killed. The lower lobe of the right lung was bound to the chest-wall; with this exception the lungs and all the other organs were normal.

Rabbit No. 10. The patient from whom this rabbit was inoculated died from chronic diffuse nephritis, with a large dilated heart, and general arterial disease. The upper lobes of the right lung contained ten nodules, varying in size from that of a dime to a small pea, and all surrounded by a very dense capsule of connective tissue. The contents of most were cheesy. The largest nodule was selected and a rabbit inoculated with 1 c.c. of the fluid obtained from dissolving the contents in sterilized water, with the exception of these nodules, and a very thick pleura over the entire right lung, both lungs were perfectly normal. When the rabbit was killed at the end of two months, about half a dozen small tubercular masses were found in both lungs, showing conclusively that the contents of the largest nodule selected contained tubercle bacilli.

Rabbit No. 11. Inoculated in the usual way with the calcareous and cheesy contents of two nodules, three-fourths and three-eighths of an inch in diameter respectively, situated just beneath the pleura at the apex of the right lung. The greater portion of the contents of the nodules was calcareous. The patient died from a gunshot wound of the abdomen. The rabbit was killed on the fortieth day; all the organs were normal.

Rabbit No. 12. Inoculated with 2 c.c. of fluid, obtained by dissolving the contents of two small nodules, about half an inch in diameter, situated in the central portion of the upper lobe. These nodules were surrounded by but little fibrous tissue. The patient from whom they were removed died suddenly of lobar pneumonia. The rabbit was killed on the thirty-fifth day, and with the exception of localized adhesions at the point where the needle entered the chest-cavity, all the organs were in normal condition.

These inoculation experiments show that while in the majority of cases no tubercle bacilli could be demonstrated in the healed pulmonary areas, still the fact that they were found in certain instances where the disease had remained latent for an indefinite period, and the nodules presented the same appearance as in the other cases, emphasized the difficulty of determining just when all dangers from old phthisical processes have ceased. Experiment No. 5 showed that the general abdominal tuberculosis from which the patient died, was due to the escape of the tubercle bacilli from the old and apparently encysted nodule at the apex of the left lung. I can recall a number of cases of miliary tuberculosis, and some of tubercular meningitis, where the only tubercular process which could be found in the body was an encapsulated nodule in the lungs, containing possibly some cheesy material.

These experiments will at least demonstrate the possible dangers which may lurk in these apparently inert masses. Experiments 4 and 10 showed tubercle bacilli in the healed areas in the lungs, and proved that even from these nodules, to all appearances completely enclosed by fibrous tissue, tubercle bacilli had escaped and caused

the eruption of miliary tubercles, which were seen about the masses in both cases. Possibly the physical organism had undergone certain changes in these cases. In Case 4 a localized bronchitis was found; in Case 10 the patient with chronic Bright's was very sick for two months before death. Both of these conditions may have favored the escape of the tubercle bacilli.

May we not here have an explanation of the sudden development of the phthisis in those cases where a localized, and perhaps forgotten, tuberculosis from which apparent recovery has been made, suddenly redevelops.

Conclusions.—I offer the following as reasonable conclusions from the foregoing studies. The microscopical examinations seem to establish that fibrosis is the only method by which tuberculosis of the lungs can be recovered from, and although they accord with well known facts, recognized as long ago as the time of Laennec, by whom the first, and without question best, description of these changes was given, I offer no apology for going over again what may seem at first sight a well-worn subject, for my endeavor has been to study the methods of the formation of this fibrous tissue and the elements from which it is derived. The gross description of the lungs which I have given is the natural grouping of those which have come under my observation.

I have been able to find in medical literature but a few statements as to the percentage of cases of cured phthisis, based on post mortem examinations. In consideration of the large number of cases from which these conclusions are drawn, I believe the time spent in this work has not been in vain.

As to the presence or non-presence of tubercle bacilli in the healed areas, as far as I know this point has never before been investigated. In all the cases examined, and from which I have made inoculation experiments upon rabbits, tubercle bacilli were found in only three instances.

There was one suggestive fact found in my examination, viz., that whenever the nodular mass or masses presenting the anatomical characteristics of healed phthisis were situated in the substance of a lobe, a broad and easily recognized band of new connective tissue passed from the nodule to the pleura through the apparently healthy pulmonary tissue. Sometimes there were more than one of these bands. At the place where the bands reached the surface of the lungs, evidences of a localized pleurisy were found, generally with adhesion of the two surfaces of the pleura. How to explain the presence of these bands is not easy. Its appearance, so often repeated, suggested that some constant and determinable influences were at work, and in the study of the lymphatics and the distribution of pigment in the lungs rests, I believe, an explanation. After consulting all the writings on the lymphatic circulation of the lungs to which I had access, two conclusions presented themselves: First, that the subject is one which had been but imperfectly investigated, and about which little is known, most anatomists dismissing the matter at short hand; and secondly, that the consensus of opinion, including such writers as Sappey, is, that there are two systems of lymphatics in the lungs, namely, those in and beneath the pleura, which empty into the bronchial glands and are entirely distinct from the others in the lung substance itself, which latter follow the vessels and converge at the root of the lungs where they also empty into the bronchial glands.

To ascertain in what direction from the point of injection inert particles, such as carbon, would be carried when introduced into the lung substance the following experiments were made upon rabbits:

Into the lung-substance, as near the centre of a lobe as possible, four healthy rabbits were injected, under antiseptic precautions, with a fifth of a cubic centimetre of sterilized water. The water injected into two of the rabbits held in suspension powdered charcoal; that injected into the other two, carmine. The rabbits were killed at the end of the third, thirtieth, and fortieth days, and microscopical sections were cut at right angles to the surface of the lungs, extending from the pleura to the root of the lungs.

It became evident that the pigment was carried from the centre of a lobe, where a large mass of it was collected, not only outward to the pleura but inward to the root of the lung—most of the pigment passing in the latter direction.

Pigment-granules were seen along the surface of the pleura only over the central mass of injected pigment, in the interlobular connective tissue, running inward from the pleura, and also in pigmented cells found in the smallest bronchi.

While no doubt some of the pigment in these cases was carried toward the surface of the lung by the bronchi and blood-vessels, the continuous lines of pigment-granules seen in some of the interlobular connective tissue would point to the lymphatics as being instrumental in diffusing the pigment toward the surface of the lungs, even to the pleura. The interlobular tissue of the lung of the rabbit inoculated with the carbon granules was beautifully mapped out by the pigment.

A study of a number of microscopical sections made of normal lungs, and of lungs in which an old tuberculosis was present, leads me to believe that the lymphatics situated in the interlobular connective tissue run toward the pleura; certainly those at least seem to do so which are situated in the outer third of the lung. The distribution of the pigment noted in these cases seems to help to explain the formation of the characteristic bands of new connective tissue which I found in the human lungs, extending from the nodules located in the central portion to the overlying pleura. In none of the sections was there noted a band extending in any other direction. Inferences might be drawn thus: The inflammatory products resulting from the destruction of tissue by the tubercular processes which have taken place in the central portion of the lungs are carried in the lymphatics which run in the interlobular septa to the pleura. There a localized pleurisy is set up; this may be the first intimation given by physical examination that tuberculosis has commenced. So also the pleuritic crepitation heard must have a special pathological significance, ante-dating often any other physical sign. In like manner, it is readily seen how the interlobular connective tissue irritated by the inflammatory products in the lymphatics increases, and so are formed the broad bands of new tissue which are noted in these cases.

My examinations also show that it is not the tubercle which undergoes healthy evolution, but the normal connective tissue of the lungs, which surrounds it, and of this connective tissue, it is the interlobular, assisted by that of the pleura which first increases, and is able to resist the advance of the destructive processes. If by any means the vessels in this tissue can be kept open, the capillaries filled with blood, fibrous processes will be established as the result of the irritation, and the active congestion. If there is any virtue in Koch's "tuberculin," high elevation, or certain indirect methods, as the pneumatic cabinet, may it not be due to the localized congestion which they excite? A microscopical examination of the lungs removed from three patients who had been treated for a long time by injections of Koch's "tuberculin," showed a most intense active hyperæmia of all the vessels in and around the old fibroid areas at the apex of the lungs. In these situations an unusual formation of new connective tissue was taking place. The microscopical appearance of these lungs differed in this respect from all others I have ever examined. When once formed, the fibrous growth acts as a bulwark to prevent the irritation and extension of the tubercle bacillus. In this way such tubercular exudation as has occurred will be rendered abortive, and even large ulcerations will be healed and cicatrized by the newly formed connective tissue. In examining the lungs which I removed from a patient who died a few months ago in Bellevue Hospital, I found in the upper lobe of one lung, a cavity the

size of a walnut. This cavity communicated with a bronchus, and had a dense fibrous lining, fully one eighth of an inch in thickness. It was filled with masses of cheesy tubercular material, which contained tubercle bacilli in large numbers. In the upper lobe of the opposite lung was an eruption of miliary tubercles, covering an area about two inches in diameter. A careful examination showed the walls of the cavity to be intact, and that it had resisted the advance of the tubercular process. In one of the larger bronchi was found a tubercular mass covering an ulcerated surface, showing that the infection must have extended from the old cavity by way of the bronchi to the opposite lung. Here lurks another danger of an incompletely healed tubercular process in the lungs, and not till every avenue of extension is shut off, and the cavity free from tubercular products containing bacilli, can we consider pulmonary tuberculosis as cured. The few encapsulated tubercle bacilli must then be rendered inert. The two healed cavities which I have previously mentioned in my cases were free from any material; their walls were fibrous looking, and contained no vegetations. The contracted cavities, which communicated with no bronchus, contained but little material. Whether this had been removed by expectoration or absorption it is hard to say.

It is a well-known pathological fact that loss of the parenchymatous elements of a tissue or organ is followed by a new growth of connective tissue to take their place. The new growth must be pathological in intensity to be effective when there is much destruction of tissue. May not this rule be applied to the lungs to explain the conservative changes which take place in them? In phthisis the pulmonary parenchyma, being of a higher grade of vitality than the connective tissue, is acted upon and destroyed first by the tubercle bacilli. The surrounding connective tissue is stimulated to increased activity by the irritation which is produced, just as occurs in other places in the body on the application of an irritant. Again, the parenchyma of the lungs being destroyed, the connective tissue must increase to fill the vacancy produced. Laennec and Bennett both describe autopsies made on private patients who had been under observation for a number of years, in whom a careful study of the physical signs indicated that cavities had formed and gradually cicatrized. At the post-mortem, the place of these cavities was entirely taken up by new connective tissue formation, and no collapse of the lungs had occurred to aid their obliteration.

Before closing this article, I would acknowledge my indebtedness to Dr. Henry S. Stearns for the photographs which he has kindly taken for me, both of the gross specimens, and of the microscopical sections.

As a summary, and a partial answer to the question with which this paper opened, I would suggest the following:

1. Out of 763 persons dying of a non-tubercular disease, 71, or over nine per cent., at some time in their life, had phthisis, from which they had recovered.

2. The new fibrous tissue by which the advance of the disease was apparently checked, and the cure effected, developed principally by round-cell infiltration of the interlobular connective tissue, which in some instances had increased to an enormous extent. Some of the new fibrous tissue was formed later by round-cell infiltration in the alveolar walls and around the blood-vessels and bronchi. Pleuritic fibrosis appears to be secondary to tubercular processes in the lung-substance. The interlobular connective tissue is the primary and principal source of the fibrosis.

3. Tubercle bacilli were present in the healed areas in three out of twelve of the lungs examined. These healed areas did not differ in their gross or microscopical appearances from those in which they were not found.

4. Thirty-six per cent. of all cases where the lungs were free from disease showed localized or general adhesions of the two surfaces of the pleura.

ON REFLEX IRRITATIONS AND NEUROSES CAUSED BY STRICTURE OF THE URETHRA IN THE FEMALE.[1]

By FESSENDEN N. OTIS, M.D.,

EMERITUS PROFESSOR OF GENITO-URINARY AND VENEREAL DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; ONE OF THE CONSULTING SURGEONS OF CHARITY HOSPITAL; OF THE NEW YORK SKIN AND CANCER HOSPITAL; OF THE MANHATTAN EYE AND EAR HOSPITAL; OF ST. ELIZABETH HOSPITAL, NEW YORK, ETC., ETC.; PRESIDENT OF THE AMERICAN ASSOCIATION OF ANDROLOGY AND SYPHILOLOGY FOR THE YEAR 1891.

GENTLEMEN: Stricture of the urethra in the female has been so rarely considered, or even referred to in works on the general diseases of females, or on the special diseases of the genito-urinary organs of the female, or even in works devoted solely to the subject of urethral stricture, that it might hence be inferred to be a difficulty so rare or so unimportant as to be of little practical consequence.

Symptoms in the female which, in the male, would be at once accepted as indicating the probable presence of urethral stricture have been often recognized and referred to under the title of "irritable bladder in the female," and attributed to causes quite independent of their possible relations to the urethra. It has even been recognized that over-distention of the urethra in such cases is one of the most efficacious modes of treatment, and yet the advantage which might result from the examination of the urethral canal for conditions which would justify such procedure, would seem to have been completely lost sight of.

The fact that stricture of the male urethra is accepted as usually due to either gonorrhœal inflammation, or to some traumatic cause, while the "irritable bladder" in the female, above referred to, occurs quite independently of any previously recognized inflammation or other injury of the urethra, tends, doubtless, to prevent the consideration of stricture as a possible cause of the trouble.

In connection with the above generally received opinion, I wish to say that I have long been convinced that the foundation, at least, of the very largest proportion of strictures in the male, consists of cicatricial deposits due to lithiasis at periods often long antecedent to the gonorrhœas to which they are attributed. I have many times detected strictures in early boyhood sufficiently developed to cause disturbances more or less troublesome in the urinary function.

In regard to the origin of organic urethral strictures, in either male or female, there is no one point more thoroughly settled in my own mind than that, whenever occurring or wherever situated, it is due simply and always to the exudation and organization of plastic lymph in the subepithelial urethral tissues, in the strictest accordance with well-known physiological and pathological laws, and is thus wholly free from any specific element or peculiarity whatever. Irritation of the urethral mucous membrane sufficient to cause the localized exudation of plastic lymph into the subepithelial structures, may, and very often does, take place through an inflammatory process of so low a grade as to be free from any pain or sensation to the subject of it. In this way, through the passage of urine in subjects of gouty or rheumatic diatheses, strictures are formed practically identical with those resulting from gonorrhœal or traumatic cause—differing only in their more chronic course, and capable of producing all the symptoms, reflex as well as local, which have been recognized as the effect of strictures of alleged gonorrhœal origin.

It is now a very generally accepted fact that some of the most distressing and obstinate of the reflex difficulties due to stricture of the male urethra are caused by comparatively slight contractions of this canal. M. Civiale, of Paris, was the first (in 1850) to call attention to this subject.[2] Thus, at page 45 of his work, in speak-

[1] Read before the American Association of Andrology and Syphilology, Washington, September 22d, in the absence of the author, by Dr. W. K. Otis

[2] Traité pratique des Maladies Génito-urinaires, par M. Civiale, p. 45, etc. Paris, 1850.

ing of the urethra, he says: "Independent of its local sensitiveness, there is another kind which may be termed the sympathetic, which, when aggravated, may awaken sympathetic response in every organ and function of the body." He then cites full clinical proof of his position.

Through a series of observations quite independent of any knowledge at that time of Civiale's views, I was able to confirm and support them in a paper entitled, "Reflex Irritations throughout the Genito urinary Tract, Resulting from Contractions of the Urethra, Congenital or Acquired," read before the New York Academy of Medicine in February, 1874. This paper, which was supported by a series of clinical cases occurring under my own observation, gave rise to considerable discussion at the time and subsequently, and it was not until two years after that M. Civiale's priority in the field was discovered by me, and publicly acknowledged. During the many years since that time, so much well-authenticated evidence has been adduced in support of the views then advanced, that their acceptance by the profession at large may perhaps now be claimed to be general.

In regard to urinary troubles in the female, simulating those which have been found often due in males to urethral stricture, the similarity does not appear hitherto to have suggested a similar origin.

The following cases are presented to show: First, that stricture of the urethra in women may occur in extent sufficient to cause reflex troubles as varied and severe as those occasionally caused by stricture of the urethra in man, and this quite independent of any recognized specific or traumatic cause. Second, that in cases of females suffering from urinary troubles which do not respond to the ordinary measures in use for the relief of such troubles, attention may be directed to the desirability of early exploration of the urethra by means of the urethrometer, or the bulbous sound, in order promptly to eliminate at least one important element of failure in the diagnosis and treatment of such cases.

CASE I.—Mrs. S——, aged seventy, in excellent general health, was referred to me in October, 1888, for treatment of frequent and painful urination, to which she had been subject from time to time for the previous two or three years, during which she passed through the hands of several well-known medical men without obtaining relief. She had been examined repeatedly for stone in the bladder with negative result, and her difficulty was finally looked upon and treated as the result of irritating urine consequent upon a gouty diathesis. Examination of the urine showed it to be normal in quantity and color, specific gravity neutral—no albumin—a few pus- and blood-corpuscles and epithelia from the bladder, and a few crystals of triple phosphate. Urination was said to occur every half hour or oftener, with pain and straining at the close of the act. Occasionally little clots of blood had been observed in the urine also at times slightly staining the linen. A careful examination of the bladder for stone failed to detect that or any calculous material. Examination with the urethrometer showed the urethra to be 34 mm. circumference at the vesical orifice, and for an inch and a half anterior—at which point it was contracted to 24 mm. by a narrow band scarcely a quarter-inch in breadth; the canal then showing a gradual dilatation to 32 mm. at external urethral orifice. The dilating urethrotome was introduced, under ether, expanded to 32 mm, and division of the stricture made at this point. During an irrigation of the bladder subsequent to this, several minute scales of phosphatic material were found, supposed to have been lodged in the urethra somewhere behind the stricture, and adding to, if not the sole cause of, the vesical irritability. The dysuria ceased immediately subsequent to the operation, and the patient was quite free from further urinary trouble, and so continued for a little more than a year, when practically the same symptoms recurred. Examination revealed a recontraction of the stricture to about its former dimensions. A redivision of the stricture to 34 mm. was made, producing equally prompt relief as in the former instance, although no calculous matter was discovered, thus proving, in a measure, the reflex influence of the stricture to have been the cause of the dysuria in both instances.

CASE II.—Mrs. W. N——, a lady from the country, aged about twenty, of very delicate features and fair complexion, married about six months, not pregnant, came under my care in November, 1889. She had a history of occasional attacks of frequent and painful urination during the previous twelve months, apparently unrelieved by medication. The symptoms were so like those of vesical calculus that her father—from whose bladder I had removed a hard stone some eight years previous—insisted upon an examination of the bladder for that difficulty. This was finally made by the family physician, who reported the probable presence of stone, as he was under the impression he had touched it, but could not be quite certain. The case was then brought to me for litholapaxy. The symptoms—frequent micturition with pain at the close of the act—which, in the beginning, came on once in two or three weeks, and lasted a day or two, gradually increasing in frequency, had now been present almost constantly for several weeks, not especially affected by motion or position; the greatest relief having been obtained by use of hot water applications. Urine of high specific gravity, strongly acid, and containing a few crystals of uric acid and a few pus- and blood cells. Examination of the bladder in my office failed to find any trace of stone. A second and more exhaustive exploration at hotel, under ether, was made with similar result. Examination of the urethra with the urethrometer was then made, with the result of demonstrating a probable normal calibre of 32 mm., and two points of stricture of 24 mm. circumference. One just within the external meatus, and the second about an inch farther down. Divulsion was then decided upon, and made under ether very carefully—first using the urethrometer made strong for such purpose, next Sampson's urethral speculum, and lastly expanding the canal with Stein's urethral dilator, very slowly and with difficulty, up to 70 mm., the entire procedure occupying fully half an hour. The urethra and vesical neck explored with the finger, but without discovering anything abnormal. The intervals of urination, which before the operation were about half an hour, subsequently were increased to three hours. Considerable pain followed the divulsion, relieved to considerable extent by hot water applications and iodoform suppositories, opiates not being well borne. The pain on urination, severe at first, felt only during the act and not after, grew gradually less, until in about a week it disappeared entirely, and the intervals of urination had increased to about four hours, when the patient returned to her home in the country, apparently well. A letter received from her after an interval of several months, contained the statement that, up to the time of her writing, she had not experienced the slightest return of her urinary trouble.

CASE III.—Mrs. W——, aged fifty-five, height about five feet three inches, weight one hundred and twenty pounds, of highly active, nervous temperament, gouty diathesis, but in fair general health. Occasional attacks of digestive and other troubles, credited to the inherited gouty vice, and for which the various anti-gouty remedies had been employed. On several occasions a course of the waters of Hombourg or Marienbad had been ordered, and taken with apparent benefit. Natural and artificial mineral waters had been taken to considerable extent at home, the turbid condition of the urine usually suggesting their use, and yielding more or less promptly to their effect. Nervous dyspepsia and other evidences of the gouty diathesis called for consideration and treatment, from time to time, up to the spring of 1888, when a voyage to Europe was made for the purpose of revisiting one of the German Spas. During some preliminary visiting in London, and while in fair general condition, she

began to be troubled with frequency of urination. The urine at first apparently clear and its passage painless, but becoming very soon cloudy, with increasing urgency and some sense of irritation, within a few hours showing a marked deposit of mucus with slight traces of blood. The services of one of the most eminent medical men of London, after a few days' trial, failed to afford any substantial relief. Suspecting the presence of vesical or urethral calculus, a skilled surgeon was called, and on hearing the history of the case, expressed himself confidently in regard to the probable presence of stone as a cause of the difficulty. A careful exploration, however, failed to detect, in the bladder or urethra, any calculus or other obstructive material. A few days of extreme suffering followed this procedure, when the acuteness of the urinary symptoms passed away; but notwithstanding a varied treatment under the best attainable medical care in London, the urinary frequency continued, with more or less pain, and after several weeks of further trial without marked amendment, she returned in a quite disheartened condition to her home in New York.

As soon as possible after her arrival, Mrs. W—— was again the subject of careful consideration by her family physicians. This finally resulted in the same conclusion, as to the nature and cause of her troubles, as that taken abroad, viz., that they were due solely to the presence of the gouty diathesis. Treatment was then pursued with this prominently in view. Moving about apparently causing but little aggravation of her urinary frequency or pain, the lady, after a time, ignoring her urinary ills as far as possible, resumed attention to her usual affairs, which were manifold.

In the early part of November, 1889, I was favored by Mrs. W——'s physician with an account of her difficulty, and soon after was invited by him to take charge of the case. During my first interview with the patient I was struck with the similarity of the account which she gave of her pains to those so often associated with reflex irritations of the urethra in the male. The chief complaint, however, was of a "grinding pain," as if the walls of the bladder, at its neck, were forcibly rubbed together with grains of sand intervening. This came on at the close of urination several weeks previously, slight at first, but increasing, and soon associated with more or less constant neuralgic twinges down the thighs, and even to the soles of the feet, especially aggravated by fatigue or mental anxiety. Felt also over the region of the bladder, and at times, when most severe, extending upward through the chest and along the sides of the neck, and sometimes terminating in a distinctly recognized sensation—not a pain, but rather as of a slightly metallic taste under the tongue. These pains and discomforts were described as distinctly following, and apparently the result of, the act of urination, and never felt except in that connection. The urine previously examined was normal in quantity and specific gravity, light in color, cloudy, odor strongly ammoniacal; microscopic examination showing pus, mucus, and vesical epithelium, but no casts. The history, conditions, and symptoms pointed strongly to a foreign body in the urethra or bladder, as the cause of the dysuria, and probably of the associated reflex neuralgia. With Professor T. G. Thomas as consultant, Dr. Henry F. Walker and my son, Dr. W. K. Otis, assisting, the patient under chloroform anæsthesia, I made first a careful exploration of the bladder and the urethra for stone or other foreign material, but with negative result; nor was any abnormal condition of the urethral or bladder walls recognized. An electro cystoscopic examination of the bladder was then made, but besides confirming previous conclusions as to complete absence of stone or neoplastic growth, only such changes in the mucous membrane of the bladder were found as are present and characteristic of mild chronic vesical catarrh. The previous introduction of Thompson's searcher, also of the cystoscopic tube, had given no indication of the urethral stricture which the significant reflex symptoms suggested. Examination with the urethrometer, however, introduced closed and turned up in the bladder to 45 mm., showed on withdrawal a urethral calibre of 40 mm. at the vesical junction and for half an inch, and then a gradual narrowing in the next half-inch of 12 mm. to 28 mm., 28 mm. for a quarter of an inch; then a gradual increase to 34 mm. at the external orifice; thus showing a urethral stricture present quite sufficient to produce both the local and reflex symptoms in practically identical and well-authenticated cases of stricture of the male urethra. With the approval of my associates I proceeded at once to restore the urethra to its estimated normal dimensions, first distending it slowly by means of the urethrometer, until Sampson's urethral speculum could be readily introduced, carrying it with this up to 50 mm.; then introducing Stein's urethral dilator and distending it up to 70 mm., when upon withdrawal my index-finger was passed readily through the urethra into the bladder. A careful exploration of the bladder was then made, especially of the parts about the vesical neck, but without detecting structural change or foreign body of any sort; very slight hemorrhage followed. The first effect of the operation was to increase the interval between the acts of urination, from half an hour at longest, to about two hours. The feeling of sand-like grinding on the vesical neck, so much complained of before the operation, did not recur, neither was there any return of the curious reflex symptoms previously described.

In short, the whole train of ills associated with the urinary act had quite disappeared; the only trouble, soreness and smarting attendant upon the passage of the urine over the distressed mucous membrane, quite severe at first, grew gradually less, and within a few days passed off entirely. For the correction of the strongly ammoniacal odor of the urine, which persisted, as well as for the catarrhal condition of the bladder, a course of Ultzmann's antiseptic and astringent injections was instituted.[1]

In carrying out this procedure the normal capacity of the bladder was found to have decreased so, that at first only about four ounces of fluid could be introduced without producing strong desire to urinate. Gradually, however, with gentle distention by means of the Alpha syringe, the capacity of the bladder was increased to sixteen ounces within the following two months. The catarrhal condition improved, and the intervals of urination increased to between three and four hours. An habitual daily irrigation of the bladder with chloride of sodium, ʒ j. to O j. of water, was then substituted for all other treatment. Notwithstanding the occurrence of decidedly gouty manifestations from time to time, for which she was under the care of her regular medical attendant, she continued to improve, until after a couple of months, during an exacerbation of dyspeptic trouble, she had a recurrence of the urinary frequency, some of the acts of urination followed by the sand-like irritation formerly the source of so much complaint. Another examination, under chloroform, revealed the fact of a recontraction about a fourth of an inch in breadth, and down to 34 mm., just within the external urethral orifice; the remaining portion of the urethra permitting the easy passage of the urethrometer turned up to its full extent, viz., 45 mm. This contracted portion was distended to 45 mm. and then divided with a blunt-pointed bistoury (to the depth of about a fourth of an inch), until not the least obstruction could be detected. The next passage of urine, which did not occur until nearly five hours after the operation, was somewhat painful from contact of the urine with the wound, but was perfectly free from the distressing symptoms previously referred to. Mrs. W—— was seen by me last on August 10, 1891, in Switzerland, returning from a course of treatment for her gouty diathesis at one of the German Spas; she was in excellent con-

[1] See Ultzmann on Pyuria, pp. 68 et seq. New York: Appleton & Co. Also Otis on the Male Urethra, p. 73. Detroit: George S. Davis. 1838.

dition and spirits, being then, as she stated, perfectly free from any urinary difficulty.

In conclusion, I would like still farther to call attention to the probable frequency of cases of urinary trouble in the female, local and reflex, due to unrecognized urethral contractions. A moiety of such cases have found relief through divulsion of the canal, or by an equally empirical gradual dilatation by the use of sounds. To what extent the latter mode of treatment, especially, has obtained, it would be very difficult to estimate, as I have yet to see any published account of it; but which may have had a much wider range than the treatment by divulsion or over-distention of the urethra, as the following incident will suggest:

One morning, five or six years ago, being in the office of my venerable and distinguished colleague, Dr. John T. Metcalfe, Emeritus Professor of Theory and Practice in the College of Physicians and Surgeons of New York, he astonished me by the exhibition of a small pocket case of short steel urethral sounds, which he said he had used for years in his practice, and which he had found to be a specific in cases of idiopathic irritability of the female bladder. The late Dr. Lewis Fisher, of New York, who was at one time largely engaged in the treatment of the nervous diseases of females, had, as I subsequently learned from him, a similar case to which he attributed similar virtues.

A few words now in regard to the diagnosis and treatment of stricture of the urethra in the female, and I have done. Unfortunately, there has not yet been discovered any guide to the probable normal calibre of the urethra in woman; nor does there seem to have been any considerable number of measurements of that canal reported, upon which reliable estimates might be based. After the discussions which have occupied the attention of genito urinary surgeons more or less for the last fifteen years, concerning the normal dimensions of the male urethra, it will now scarcely be a question of its probable individuality in woman. My own observations, up to this time extending to not more than twenty-five or thirty cases—none of which have been noted with absolute exactness—have still proven to me that there is a wide range in the normal calibre of the urethra in woman, covering at least 15 mm., *i.e.*, from at least 30 to 45 mm. circumference, and without regard to the physical proportions of the individual; also that the urethra, aside from an occasional contraction of two or three millimetres at the external meatus, is of nearly uniform size. In making examinations it will be necessary to use the urethrometer or the bulbous sound. The latter will doubtless answer to determine the absence of strictures, and to localize them in the majority of cases when present; but for a complete diagnosis, in many cases, the urethrometer will be essential. This instrument should be introduced closed, well into the bladder, and fully expanded; then, on withdrawal, turned down until it will pass the internal meatus, noting the calibre at this point, and subsequently the obstructions, if any are met; then locality and degree until the bulb emerges from the meatus externus; exactly in the same way that it is recommended to use the urethrometer in examinations of the male urethra.

Divulsion of stricture in the female may be claimed as a very different and greatly less serious operation than the same procedure for stricture of the male urethra—to which, as a rule, I am decidedly opposed. In perhaps a dozen instances I have carried the distention of the female urethra up to seventy millimetres circumference, thus to the point of admitting my index-finger, and never, save in a single instance, finding any constitutional reaction resulting, nor any inconvenient loss of control of the urine. This exception was in a lady of seventy, where the urethra was distended for extraction of a phosphatic calculus, and where the walls of the bladder were found so coated with calculous material that great and prolonged distention by the finger became necessary, working with the forceps, lithotrite, and scoop before its complete removal was accomplished. The vesical sphincter was quite disabled for several days, and for several months after a little jet of urine would accompany the act of sneezing, coughing, or suddenly assuming the sitting posture; but finally the normal control was restored. The tendency to recontraction in strictures of the female, when treated by over-distention or divulsion, has been most marked, in several instances calling for a repetition of the procedure. It seems to me probable that in a very large proportion of the troubles due to stricture of the urethra in the female, gradual dilatation may be resorted to with benefit, and thus come readily within the scope of the general practitioner, to whose notice they usually come in the first instance. The symptoms once relieved, subsequent periodical dilatation may be readily practised by the patient through the self-introduction of the urethrometer into the bladder, the instrument then expanded to the required degree and gently withdrawn. I now recall the instance of a lady once under my care, whose strictures were divulsed with relief to a troublesome frequency of urination, who uses the urethrometer in the way above described without difficulty or discomfort, every three or four weeks, with immediate relief to the urinary frequency, which was thus apparently shown to have been dependent upon slight recontraction of the stricture.

By A. M. PHELPS, M.D.,

New York.

The question of a suitable spinal support in lateral curvature of the spine and convalescent cases of Pott's disease, has been before the profession from the earliest time, and not until Dr. Sayre devised the plaster-of-Paris corset did we have a brace that accomplished nearly all that is desired in a support.

The plaster-of Paris corset I believe to be one of the most efficient of supports. It certainly has the advantage of cheapness, and it is well adapted for use in clinics and dispensary practice. It has, however, the disadvantage of weight. Steel braces have been made. Many of them, when suitably applied, furnish very good results. Dr. Vance constructed, to take the place of the plaster-of-Paris corset, a paper corset.

If the profession could have at their disposal a corset which combines strength, durability, porosity, and lightness, it would meet a long-felt want. I had heard something of the wood corset, but knew nothing of its construction. Therefore, three years ago I visited Europe for the express purpose of learning the details of its construction. On my return, I presented the corset at a meeting of the Surgical Section of the New York Academy of Medicine.

I visited Dr. Waltuck, of Odessa, Russia, and from him personally I learned the details. after several days of hard work. I found that Professor Lorenze, of Vienna. had been using the corset for some time, and was much pleased with it. At that time, however, many of the corsets proved to be inefficient on account of errors in their construction. We have used the corset constantly since that time, and with the modifications which we have made, it is the most efficient, comfortable, and suitable spinal brace that I know of.

It has been with the greatest difficulty that we have succeeded in getting the proper materials for constructing the corset, and even now it is cheaper and better to import the wood from Vienna. The spruce timber which grows there makes a better shaving than any timber that we have attempted to use which grows in America. It is tougher, and works better with the glue.

The materials necessary for making the wood corset are: One dozen plaster-of-Paris bandages; one tight-

fitting shirt, fifty pounds plaster-of-Paris, two pounds oakum, two yards of raw unbleached linen, a blue pencil, one pound of Cologne glue, a little glycerine, a knife for splitting wood, a glue-pot, a hammer, a large clothes brush, some towels, two sandbags, a quantity of wood shavings, some shellac, an eyelet punch, a number of eyelets, and hook lacings, and two yards of knit shirting.

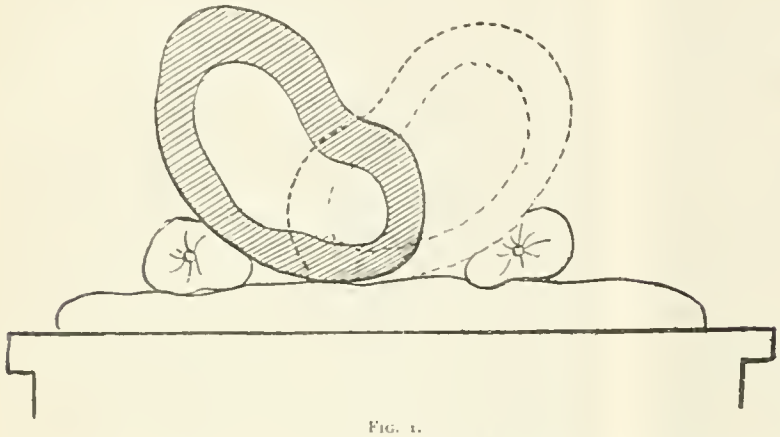

Fig. 1.

All of these articles are kept in stock by Messrs. John Reynders & Co., New York, who have kindly imported for me such materials as could not be procured in New York.

The Details of the Work.—Suspend the patient after the tight-fitting shirt has been applied. Indicate, with the blue pencil mark around the body on the shirt, the length of the corset desired. Apply the plaster-of Paris bandages as in making an ordinary plaster-of-Paris corset. When the plaster is set, remove it from the body by cutting it down in front. Strip out the shirt from the corset, when the blue pencil marks will be seen on the inside of the plaster corset. A few turns of the plaster bandage around the plaster corset is necessary. Put in a large dish a quantity of oakum picked up finely. Mix with this a quantity of plaster of-Paris. After having greased the inside of the corset with vaseline, stir water into the plaster-of-Paris and oakum until it is of the consistence of thick mud. Apply this over the inside of the corset to the thickness of three inches. After it is set, remove the corset, and a perfect cast of the body will be the result. The blue line will be transferred from the plaster mould to the cast. The oakum is put in the plaster to facilitate the modelling, and also to make the cast tough, because considerable hammering has to be done upon it. The cast should dry two or three days in a temperature not exceeding one hundred and fifty degrees. Any imperfection in the cast should be remedied with plaster-of-Paris, building out such points over the breast and hips and deformed portions as may seem necessary to make an artistic corset. Cover the cast with raw linen which has been wet for the purpose. Some difficulty will be experienced unless the workman has seen the work done.

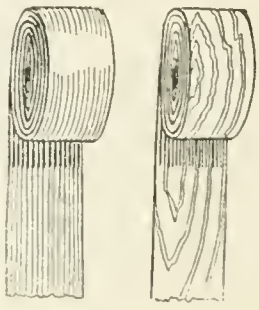

Fig. 2. Fig. 3

The cast is placed on a table with the sandbags, as seen in Fig. 1.

The wood from which the corset is made is taken from the edge of a plank the grain of which is as seen in Fig. 2. Fig. 3 shows imperfect grain. The grain running as in Fig. 2 makes a tough strip that will bend as seen in Fig 4. When the grain runs as in Figs. 6 and 7 and the wood is bent, it will present the appearance of Fig. 5, which has an element of weakness.

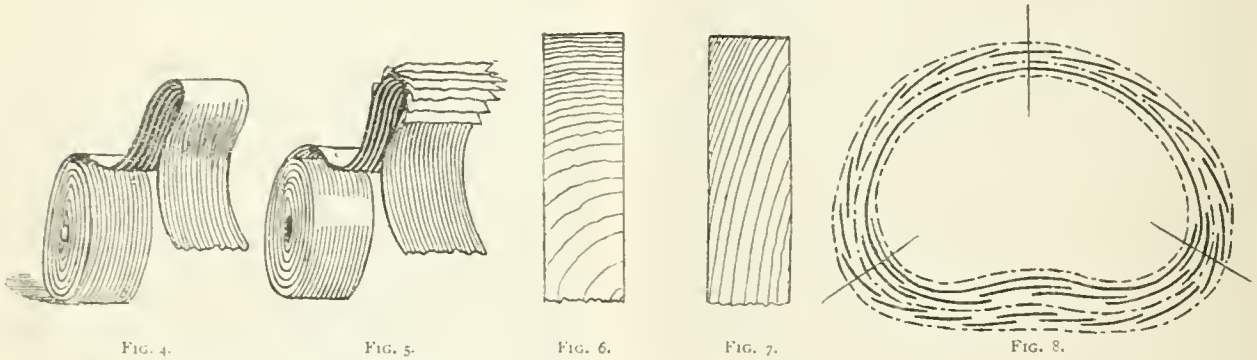

Fig. 4. Fig. 5. Fig. 6. Fig. 7. Fig. 8.

The layers of wood and linen are explained in Fig. 8, the dotted lines being linen, the black lines wood, and it will be seen that there are three layers of linen and two of wood in the front of the corset, with three layers of linen and three layers of wood in the back and side.

Over the hips extra pieces are put in, making it even thicker, which will be explained later.

The cast is now laid with the back up. Draw three longitudinal lines, one in the centre in front, and one on each side, dividing the cast into three parts. Cut several strips of wood in lengths long enough to overlap the lateral line two inches.

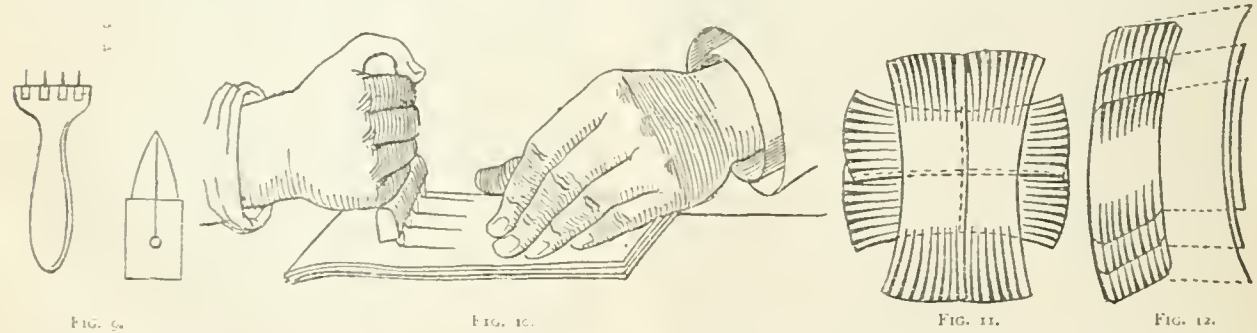

Fig. 9. Fig. 10. Fig. 11. Fig. 12.

With the tool, Fig. 9, split the ends of the wood as seen in Figs 10 and 11. The object of this is to allow the ends of the wood to spread or to overlap, so as to fit all inequalities, as seen in Figs. 11, 12, 13, 14, and 15. Prepare the glue by soaking it in water over night, then melt it. To a pot (holding one quart) of glue, add one tablespoonful of glycerine. Dip the glue-brush into the glue, wipping it as dry as possible on the edge of the pot so as to use the least possible quantity.

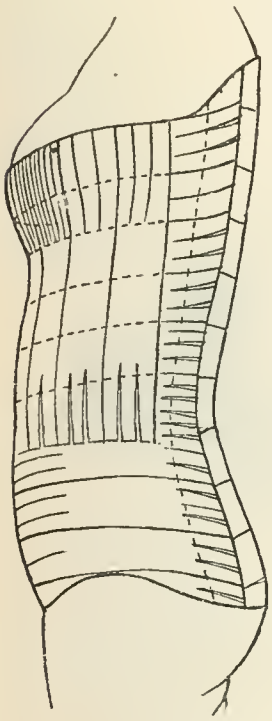

Fig. 13.

Fig. 14.

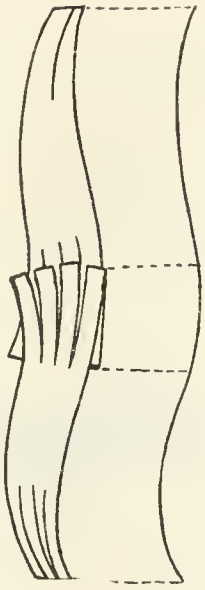

Fig. 15.

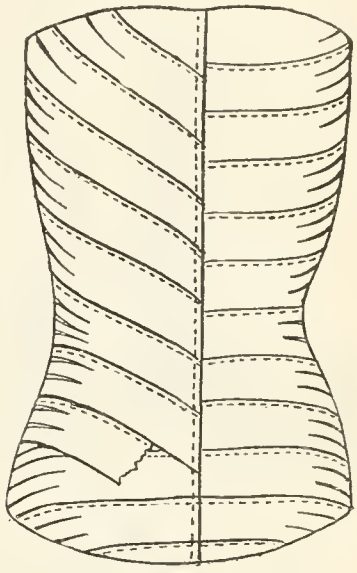

Fig. 16.

A strip of wood is covered with glue, and the brush drawn along the part of the cast where the wood is to be laid, beginning at the top of the cast with a transverse layer; strip after strip is applied, and overlapping the strip above one-eighth of an inch. Cover this layer of wood with the linen and glue, and hammer the whole together. Turn the cast on the side, and working from the centre in front, put the strips on horizontally, overlapping the strips already laid on, two inches. Cover this with linen, lapping on the back two inches. Finish the opposite side in the same manner. See Fig. 16.

Beginning in the back, put on the strips longitudinally, overlapping four inches in the centre of the cast from the top and bottom. See Figs. 17, 18, and 19.

Hammer the wood well together with an ordinary shoemaker's hammer. Now stay the corset with wood, as seen in Figs. 17 and 18, over the hips, and also strengthen the corset by putting on another layer of wood diagonally from the shoulder to the opposite hip, meeting at a point in the centre of the waist. Cover the entire work with linen, putting the least amount of glue on the wood before the linen is applied. After twenty-four hours the corset can be removed from the cast, fitted to the patient, and sent to the trimmer, who will treat it in the following manner. Corsets made according to the method followed at the time I observed the process were not as perfect as they should be.

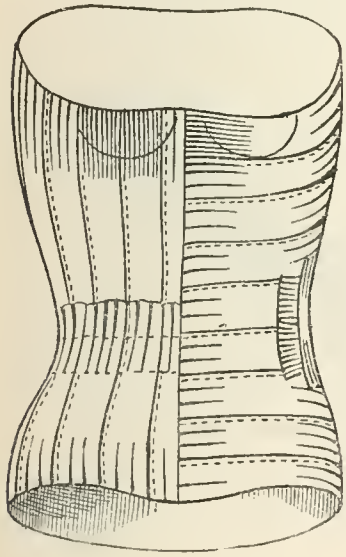

Fig. 17.

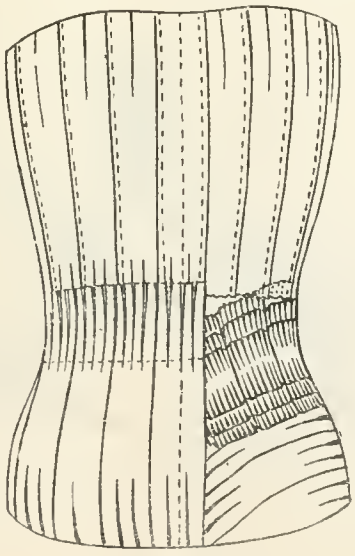

Fig. 18.

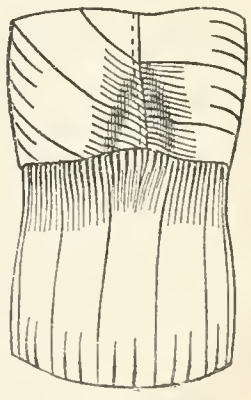

Fig. 19.

1. The slightest excess of glue moistened by the perspiration of the body coming in contact with the shirt or the skin, was exceedingly disagreeable. 2. The perforations in this corset weakened it, and allowed the glue to exude during perspiration.

To obviate all this, I had the corset perforated, as seen

in Fig. 20, in which perforations eyelets were punched. A special machine facilitates the perforating and the punching of the eyelets. The lacings are stitched on as in Fig. 20. Trim the top and bottom with kid. The entire corset is shellacked inside and outside with two or three coats of shellac, which renders it impervious to moisture, the eyelets ventilating it perfectly.

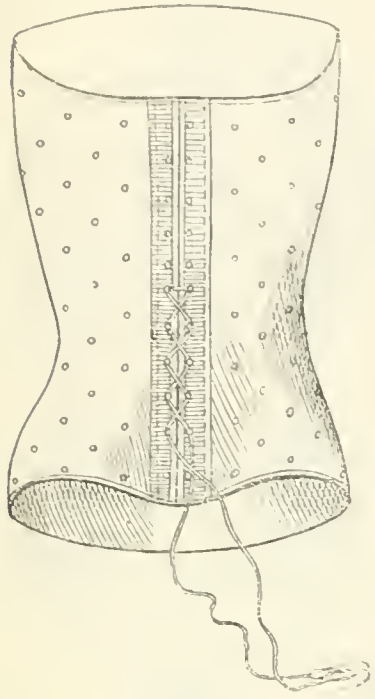

Fig. 20.

A corset made as I have described, it will be observed, differs from that of Dr. Waltuck in the layers applied as seen in Fig. 8. It is no better, but somewhat easier to make.

The improvements which I have made in the corset consist in shellacking it on the inside and outside, and putting in the eyelet-holes, eyelets, which add to the strength of the corset and ventilate it perfectly.

An ordinary corset, for an adult, weighs from one to one and a half pound. They are very durable, very comfortable to wear, and thus far I believe that they are the best spinal braces yet devised.

I have made from the paper used in the manufacture of boats, a corset which answers the purpose equally as well as the wood corset. It is much lighter, and seems to be as durable, and I am not sure but it will take the place of the wood corset. Time will determine. The process of making the paper corset is similar to that of making the wood corset, so far as making the cast is concerned, after which the cast is sent to the paper-boat manufacturer, who applies the paper according to the process employed in making boats.

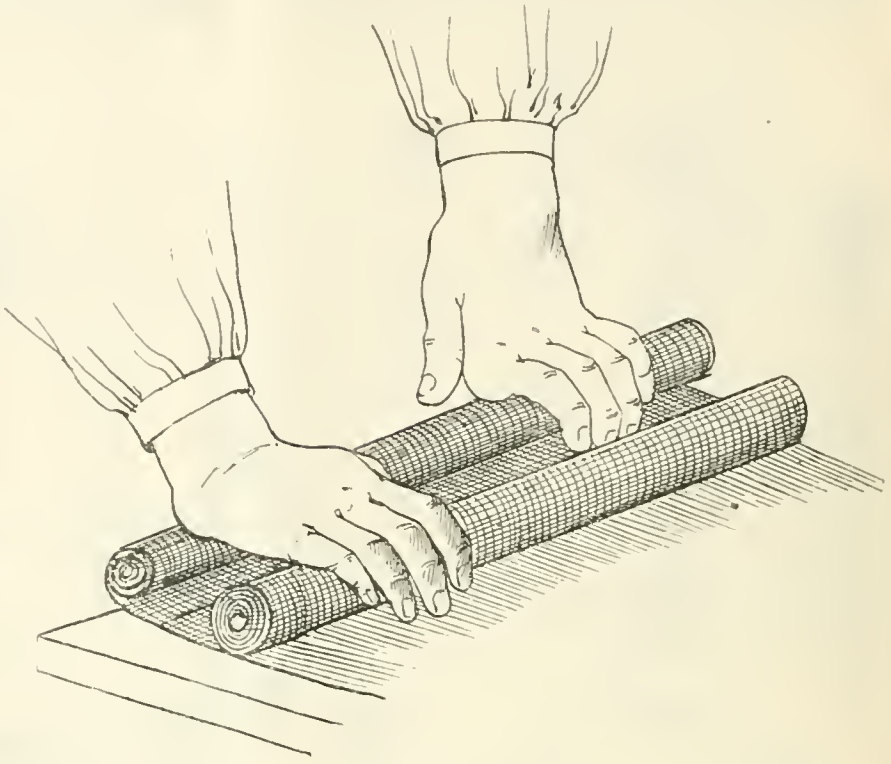

Fig. 22.

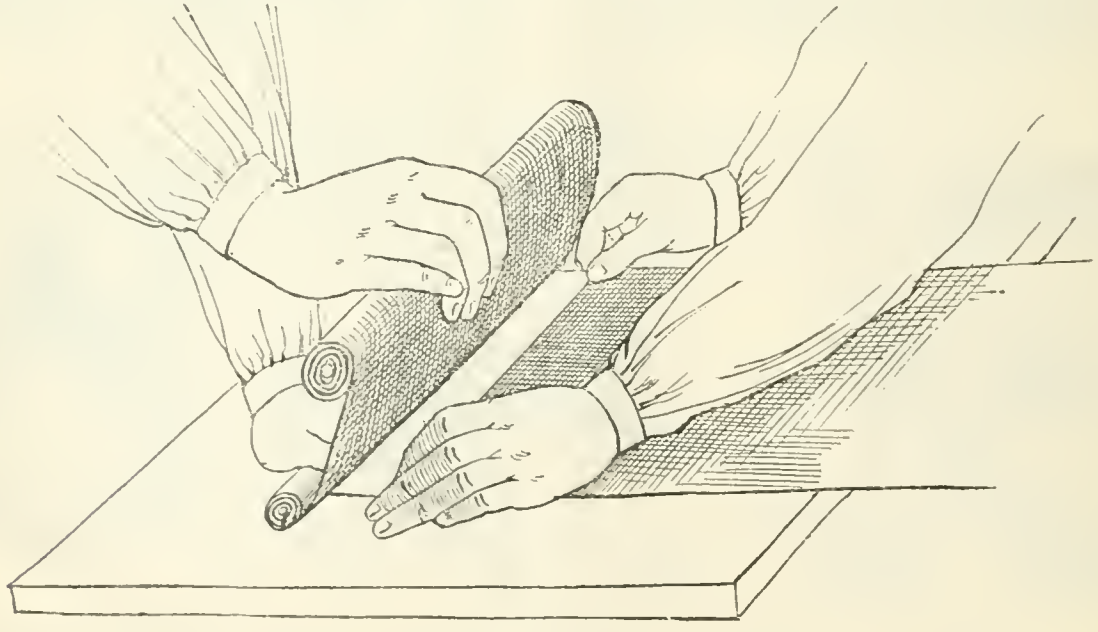

Fig. 21.

Another use to which the wood shavings are applied is in working them with plaster-of Paris in the treatment of fractures or osteotomies or excision of joints. Being thin

and narrow, they admirably adapt themselves to the parts, and the plaster-of-Paris holding them in place, they fit more accurately than any mechanic could shape a solid piece of wood to fit.

Again roll two layers of crinoline, between which wood strips have been placed, as shown in Figs. 21 and 22.

Roll up four yards of this, as seen in Fig. 22. With a saw, cut this into rolls four inches in length. Immerse one of these bandages in water, and it will be found an admirable dressing when applied to a limb in cases of joint disease, or where a slight support is required to hold a limb in a proper position The starch of the bandage soon hardens, so that we really have a starch bandage reinforced by wood shaving.

There are many cases in surgery where this bandage can be used to great advantage, and applied over surgical dressings it takes the place of plaster-of-Paris. It is light and just as strong as plaster-of-Paris, and it has the advantage over the starch bandage of keeping its position after it is applied, even before it is dry.

The corset is somewhat difficult to make. It requires a good worker in wood and glue, and a plant for doing the work.

It would hardly pay a general practitioner, who possibly would not use more than four or five corsets during the year, to go to the trouble and expense of making his own corset. If those gentlemen who desire to use the corset will make a plaster-of-Paris corset as described in the beginning of this paper, and send it to the workshop of the Post-Graduate School and Hospital, the men there will make the corset, and Messrs. John Reynders & Co. will satisfactorily trim it.

I will say, by way of parenthesis, that the corsets, when completed, can be covered with silk or with stockinet, or they can be left in the linen finish. They are not so warm for summer use in the linen finish.

Clinical Department.

MALIGNANT NOMA.

By A. H. HUBBARD, M.D.,

FUERTE, MEXICO.

I find the following in my note-book for November' 1885 :

I was called at midnight to see a boy, eight years of age, said to be crying bitterly from pain in the right cheek. On my arrival at the place I found the boy with his face wrapped in woollen cloths, on removal of which a mass of putrid flesh came away, leaving a hole in the cheek two inches in diameter.

There were no signs of inflammation ; his mother said he had complained of pain in his cheek since the afternoon before, but as there was no inflammation she paid no attention to it. The parents are both of pure Indian blood, and manifest perfect health ; they say their child never suffered a day's sickness in its life.

I dressed his face, gave an anodyne, and returned to my office. At daylight I was called in haste, the messenger saying the boy was crying bitterly from pain in the other cheek. On my arrival I discovered a dark spot in the centre of the cheek, the size of a five-cent piece. I applied carbolized cotton to the inside and a charcoal poultice to the exterior, and left to return in two hours. On removing the dressing at my next visit, to my astonment a piece of the cheek, about two and a half inches in diameter, came away with the dressing. There was no inflammation. The gangrene formed a line of separation and came out, leaving ragged edges. While I was redressing this wound the boy complained of pain in the end of his nose ; in two hours' time his nose was enveloped in gangrene.

The boy died in forty-eight hours from the first attack.

A case of symmetrical gangrene from pyæmic embolism. What was the cause ? I find nothing recorded in books of a like nature. Has anyone among the profession ever seen a case that compares with the above ?

TOTAL ABSENCE OF ALL ORGANS OF REPRODUCTION.

By L. B. SNOW, M.D.,

CLEVELAND, O.

The following case called upon me for relief of what she supposed to be an imperforate hymen. Mrs. F— —, German American, twenty-three years of age, the oldest of a family of seven children, four girls and three boys, all of whom are well developed and perfectly formed as far as known. The two oldest sisters, aged sixteen and twenty, respectively, are menstruating regularly. The family is of exceptional good health. No deformities occur in the family history. Mrs. F—— has been in good health during her life, except the seventeenth, eighteenth, and nineteenth years, during which time she was under medical care a greater part of the time, to establish her menses and regain her health. The latter returned, and her physician told her not to be at all uneasy, the other would come along in due time. Mrs. F——, now having been married three weeks, presented herself as above stated. Upon examination I found her difficulty, and the following day called Dr. C. B. Parker and Dr. C. A. H. Anderson to see the case with me. An anæsthetic was given and a complete examination made, with the following results :

Height, 4 feet 8 inches ; weight, about 105 pounds ; fair complexion, dark hair and eyes. Features slightly masculine, with a slight growth of fine hair on the cheeks, upper lip, and point of the chin, with a few coarse whiskers which add to her masculine appearance, but not more than is seen in many women. Narrow across shoulders, feminine arms, but rather masculine hands, owing probably to her life of labor. Body and thighs decidedly those of a woman, except a rich growth of coarse black hair about 1½ inch in width, extending nearly the entire length of sternum, but none around the nipples or breasts, simply a strip as though transplanted there. Breasts quite well developed, but not large. Round, full hips and thighs, and mons veneris decidedly feminine ; feet and legs below the knees muscular and rather masculine ; external genitals, labia majora and minora, meatus urinarius, and hymen perfect, but no glans clitoris could be found. The centre of the hymen looked as though a puckering string had been put in and drawn down tightly, or shut off entirely. Upon rectal bimanual examination, there could be found no trace of a vagina, uterus, Fallopian tubes, or ovaries. It might be said there was a slight band transversely across the pelvis, where the tubes should be, but that was as much imaginary as otherwise. At the extreme left was a slight nodular feeling between the rectum and abdominal wall, but it was not marked and had no resemblance or appearance to an ovary. The patient having been well prepared, the bowels and bladder being empty, and with thin abdominal walls, there could be no liability for mistake or error in diagnosis ; and it was the consensus of opinion that it was a case of total absence of all organs of reproduction of either sex, but with perfect external genitals of woman.

This woman being brought up in strict lines, did not know that she was different from other women, only that she did not menstruate. She says she never had an amative passion and doesn't know what it is. Has had some headache which might almost be called periodical, but with no regularity.

I submit this case without comment as I have been unable to look up the literature on the subject extensively, and do not know how often such cases occur ; but from what I can find it is certainly a very rare case.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 9, 1892.

A SPEEDY CURE FOR THE INFLUENZA.

DR. JOHN CRERAR, under the above title, describes a method of treatment which is based, he says, on the microbic theory of the disease. His object in treatment is to put the tissues and fluids of the human organism in such a condition that they will not furnish a suitable nutrient medium for the growth of the specific microbe, or, at least, will antagonize the poisons which it produces. He conceived the idea that this would be best done by increasing the alkalinity of the blood; for this purpose he used bicarbonate of potash.

"This salt," he says (*The Lancet*) "has many advantages. It is not unduly stable to make it difficult to break up in the system. It is also readily eliminated, and thus soon leaves the system; so that the danger of potash-poisoning is reduced to infinitesimal proportions. Having found this salt to answer all my purposes, I have not looked for another, although, according to my theory, other remedies of a similar nature might easily give like results. I give liberal doses (thirty grains) in a teacupful of milk every two or three hours. I add a few drops of the tincture of capsicum, but this is not at all essential.

"A word or two of caution. In two or three cases the action of the heart was weakened to an unpleasant degree; but digitalis and the aromatic spirit of ammonia quickly restored normality. Diarrhœa also sometimes supervenes, but is effectually met by Dover's powder. In cases where weakness was induced by previous disease, or where some other disease was a concomitant, or where pregnancy existed, the action of the remedy was somewhat retarded, but not rendered by any means less certain. Where the salt was intermitted too soon, the symptoms returned; but they readily gave way again on the resumption of the treatment. I trust that those who have the opportunity will test the accuracy of my statements by careful clinical observations, as I feel confident they will obtain equally favorable results; for the remedy acts uniformly and satisfactorily; *tuto, cito, et jucunde.*"

We believe that physicians in this country have found salicylate of soda a very efficient drug in influenza.

THE VENTILATION OF THEATRES.

OUR esteemed contemporary *The Lancet* undertakes many altruistic and scientific tasks. Among the latest is an inquiry into the "Ventilation of Theatres and Places of Public Assembly." This inquiry is not yet completed, but we have no expectation that it will be extended so as to reach this city or country. We trust, however, that its results will not be without use to those who build, and those who occasionally occupy, places of amusement and instruction in the United States. We have in the city of New York about twenty-five theatres, besides a very large number of halls and other places of meeting. In our theatres alone there is probably a nightly population of over twenty-five thousand, and each one of this number is for two or three hours poisoned with bad air. We doubt if there is a single theatre in the city whose ventilation is even reasonably good, while in some of the most frequented and popular it is execrable.

Of course very few people relatively spend enough time in the theatre to suffer any serious illness in consequence. The ventilation of theatres is a problem that does not appeal to the masses, perhaps; nevertheless, there is no reason why it should not be taken up and solved in an efficient manner. We understand from the commission report of *The Lancet* that there are at present only a very few theatres or opera-houses in the civilized world which are efficiently ventilated. The first of these is the Grand Opera House at Vienna, and the last is the Amphitheatre of the New Sorbonne in Paris.

MULTIPLYING MEDICAL JOURNALS.

WE quite agree with the esteemed *Medical Mirror* that local medical journals have a useful function, and that every doctor, medical college, and society has a perfect right to have his or its organ. It sometimes appears, however, as if what is theoretically right and what is practically best are not always identical. It costs money and time to publish and edit a journal, and of these two things doctors do not have much to spare. If, therefore, the energy scattered in the production of sixteen periodicals were concentrated into one, the results would be better for the profession at large, though less prominence might be given to certain aspiring institutions or individuals. There is one English weekly containing fifty-eight pages of reading matter and having a circulation of seventeen thousand. It secures better results than if the same matter were dispersed through a number of small journals. The same may be said of metropolitan medical journals on this side of the Atlantic with even larger circulation and wider areas of distribution and supply.

THE SIGNIFICANCE OF EYE-STRAIN.

WE can all recall how in past years certain specialties have had a popularity which was peculiarly great and striking. At one time it was, perhaps, obstetrics, at another gynecology, or rhinology, or some special branch of surgery. The basis of these fits of popularity has lain in the fact that enthusiastic gentlemen at times succeed in persuading the profession that a majority of severe and all minor ills are due to a certain special cause At one time this was ferments in the stomach and yeast-plants in the blood, and meat and hot water was a panacea; displaced wombs and sensitive ovaries, hypertrophic turbinated bones, atonic colons, and fissures and over-sensitive prostates have all been held up at times as the chief of pathogenic sinners.

No offending and pathogenic viscus has had more ardent champions than has the eye; yet one of its defenders has recently asserted in the *Medical News* that, despite some years of presentation and argumentation, the great medical discovery of eye-strain is still ignored. Eye strain, we are told, will cause anæmia, headache, migraine, vertigo, anorexia, dyspepsia, constipation, neurasthenia, hysteria, and insomnia, all of these being extremely common and unpleasant ills; yet people go on suffering from them or getting cured in other ways when glasses will quickly remedy everything. According to the doctrine of our contemporary a major part of the civilized community should be wearing glasses to correct an astigmatism or hypermetropia. Instead of taking tonics and aperients, the dyspeptic needs a quarter of a dioptra correction for his right or left eye, which correction may after a time be reduced to an eighth.

Perhaps one reason why the profession has ignored the "great discovery" somewhat is because there is an uncertainty as to what the discovery is. The dispassionate observer notes that some eminent ophthalmologists find the trouble always in the refraction, others always in the muscles, and each report a remarkable series of successful cases.

It also happens that in many cases headaches, vertigo, insomnia, nervousness, and constipation get well spontaneously under the influences of natural causes, or perhaps through the administration of homœopathy and suggestive medication. Therefore we do not feel so much surprised or so keenly chagrined as do some of the apostles of a spectacled civilization over the fact that a great medical discovery is being ignored. The profession desires that the discovery be established beyond doubt and explained in unequivocal language. Then it will accept it.

CASTRATION FOR NEUROSES AND PSYCHOSES IN THE MALE.

It has often been suggested that it would be quite as reasonable to castrate the male for nervousness and hypochondriasis and neuralgia as to remove the ovaries of woman for analogous troubles. Dr. J. J. Putnam reports a case in which this has been actually done, and the results suggest a field of work for the andrologists which they should hasten to utilize. The case referred to was that of a man now forty-one years of age. He had been unbalanced all his life, and especially so since a severe blow on the head in childhood. The operation was performed three years ago. For some years previous he had been a dipsomaniac, and excessively and openly erotic; and for a time it had been necessary to confine him in an asylum.

The castration was done at his own urgent desire. His friends confirm the statement which he himself makes, that his mental condition improved to a marked extent. He is at present, says Dr. Putnam, unreliable and suspicious to a considerable degree; but his desire for liquor and his erotic tendencies have been absent since the operation, and his disposition has been quieter, so that he is able to live alone and take care of himself, though requiring more or less supervision.

If castration were in the hands of unsympathetic and ambitious female surgeons, the imagination would be a little staggered at the possibilities which a successful case like the above suggests. As it is, we doubt if the operation will become in any way as possible as removal of the tubes and their incidental attachments, although in both instances the operations are founded upon equally irrational and absurd principles.

THE ULCER OF THE EMIN-PASHA-RELIEF EXPEDITION.

Surgeon T. H. Parke gives a most graphic and striking account of what he terms the ulcer of the Emir-Pasha-Relief Expedition (*The Lancet*, December 5, 1891). The most formidable pathological obstacle to the success of the expedition, he says, was the ulcer in question. The disease was first noticed after the party left their base of supplies at Yambaya and began their march through the primeval forest. There the mechanical obstacles which nature had imposed along their path, the permanent exclusion of the sun's rays, the stifling atmosphere reeking with vapors exhaled from the decomposition of enormous quantities of rank vegetable matter, the physical depression produced by prolonged and wearing muscular exertion without an adequate supply of food, the mental depression consequent upon the apparently hopeless character of the task which had been set, all combined to lower the physique of the men to an extreme degree. Under these circumstances the scratching of the smallest papule, the bite of a flea, a louse, an ant, a tick, a "jigger," the more impressive attentions of a mouse or rat, the sting of a hornet, the puncture or scratch of a thorn, the abrasion of cuticle produced by a rub against a projecting stump or branch of a fallen log, or sharp-cornered stone, or the vicious puncture of one of the wooden spikes (makonga) which the watchful natives placed in the pathways as they approached their villages—any one of these agencies produced a breach of continuity of the surface which not only made no attempt at spontaneous repair, but formed the centre of a rapidly spreading ulcer. As the lower extremities were mostly exposed to small injuries, and are placed by nature farthest from the centre of circulation, the necrobiotic process displayed there its most destructive ravages.

Rapid phagedenic ulceration spread from the point of injury, rapidly involving the soft parts and the bones. As the march had to be continued, and as the food was scarce and insufficient, but little could be done for the relief of the sufferers, who were, for the most part, natives.

When a place was finally reached where there was food in abundance and opportunity for rest, even the worst cases got well with surprising rapidity. The ulcers were treated antiseptically as far as the means allowed. Permanganate of potash and carbolic acid were applied, and when the store of these agents was exhausted, gunpowder was found to act exceedingly well.

The Influenza in Great Britain has apparently begun to decline. On the Continent the epidemic is present in St. Petersburg, Berlin, Vienna, and Paris, as well as in many other large towns. The number of cases reported in Berlin is over forty thousand, and in Hamburg the death-rate has risen enormously.

A PERMANENT "RECORD."

We frequently have requests from our readers for information concerning some subject that has been treated of in the columns of the Medical Record one or two, or, it may be, ten or twelve, years ago. They write that they remember having seen it, but that they were not especially interested in the subject at the time, so did not save the journal; now, however, something has occurred to draw their attention to the matter, and won't we be so kind as to send a copy of the journal containing the desired paper, or, may be, a transcription of the article itself.

But why don't our friends save their paper? After they have read it each week, why not lay it aside on the bookshelf and at the end of every six months have the twenty-six numbers bound? The expense of a plain binding is very slight, and the satisfaction of being able only once to put one's hand on a desired article immediately, without the trouble and delay of writing to the editor and asking him to do it, would be worth more than the cost of binding many volumes. Back numbers of the Medical Record are growing more and more scarce every day, and those who have saved their numbers from the beginning have a valuable medical library in them alone.

The Medical Record was not named carelessly, but purposely, and with a view to what it was intended to be—a record of medical happenings and discoveries to which one could in the future turn to learn of all that science had done for the relief of suffering humanity. And now, in looking over the quarter of a century and more since the first number was issued, we feel that we have proven our right to the name, and that these forty volumes are really what their title claims for them—a permanent Medical Record.

THE ESOCARDE.

In 1883 Dr. Salaghi, of Bologna, presented to the Academy of Medicine of Rome a plan for combating various circulatory troubles of cardiac origin by means of rhythmical compression of the peripheral circulation. The idea was that by squeezing the capillaries and veins the blood would be pushed along and the labor of the heart lightened. After making various ingenious experiments with artificial circulations and upon lower animals, he devised an apparatus which he calls an "esocarde," and which he has successfully applied to the treatment of heart disease and various other ailments.[1] The instrument consists of a number of bands which surround the abdomen and base of the thorax. To their ends are attached weights, so that they can be tightened or relaxed at will. In using it the patient lies upon a bed in the supine position. The main work of the apparatus is directed to affecting the portal circulation, since that is thought to be best adapted to mechanical influences. The "esocarde" is indicated in conditions of weak heart and low arterial tension, from mitral disease especially. It is contraindicated in aortic stenosis. Prompt and happy results from its use have been obtained in heart disease, and also in other conditions attended with low arterial tension. Dyspepsia, chorea, chlorosis, neurasthenia, and fevers are among the diseases over which the ingenious Italian's supplementary heart obtains, he asserts, a rapid mastery.

The frog is supplied by nature with an esocarde in the shape of a lymph heart; but it is supposed that the human system has passed beyond the cruder mechanism of reptilian organisms. If we have got to go back, however, to esocardes, Dr. Salaghi's invention will probably fill the need.

[1] Bullettino delle Scienze Mediche de Bologna, 1889-90, Journal de Médecine de Bruxelles, November, 1891.

THE THEORY OF GROUPS

Some ingenious and mathematical mind would find profit in studying the facts and causes underlying the appearance of medical or surgical cases in groups. The phenomenon is so frequent that almost every physician gets superstitious about it. If he meets a fracture of the neck of the femur one day, he feels sure of seeing another within a week. If a baby swallows a pin to-day, the neighbor's child will swallow its mate to-morrow. If the surgeon is called to an appendicitis on Monday, he will see another on Saturday. A lady goes into a particularly delicious and classical type of hysteria, and presently the doctor is treating half a dozen such cases, and is deeply impregnated with the odors of valerian and lavender.

These coincidences are constant and striking, and suggest the existence of some subtle underlying natural law.

Is it perhaps a conservative effort on the part of nature, that having equipped the doctor with a special and fresh experience, she furnishes him at once with opportunities for its practical use? Or is there some highly spiritualized non microbic form of contagion by which the breaking of a bone in one individual leads to a similar calamity in another? Or may there be somewhere in that higher department of mathematics which deals with the fourth dimension of space and the unity of elemental matter some law of accidents or Pythagorean formula which will explain it all?

We are persuaded that our readers ought to study the matter further, so that in time medical science may furnish a satisfactory theory of groups.

A New Method of Measuring the Capacity of the Stomach.—At the recent Italian Medical Congress, Forlanini (*Rif. Med.*, October 24, 1891) proposed a new method of ascertaining the presence of dilatation of the stomach. He passes an œsophageal sound into the stomach, and by its means distends the organ with air, in no case using a pressure of more than seven or eight centimetres of water; the air is then withdrawn by means of an aspirator and its volume ascertained. By always using the same amount of pressure when injecting, the effects of any treatment on dilatation of the stomach can be readily ascertained.

Journalistic Changes.—Dr. Brooks H. Wells will hereafter edit the *American Journal of Obstetrics*, in place of Dr. Mundé, who has so long and successfully conducted this journal. Dr. John A. Fordyce succeeds Dr. Morrow in the editorship of the *Journal of Cutaneous and Genito-Urinary Diseases.*

News of the Week.

The Alumni of the College of Physicians and Surgeons are to have a dinner at Delmonico's on Saturday evening, January 16th. The Council of the Association think that the recent actual union of their Alma Mater with Columbia College should be thus commemorated. The following gentlemen have consented to act as the dinner committee: Drs. George M. Lefferts, R. F. Weir, F. P. Kinnicutt, M. A. Starr, George H. Tuttle, and Charles Hitchcock.

The Hospital Saturday and Sunday Association.—In a circular issued by the Executive Committee of this Association it is stated that although the annual sums collected each year were larger, the number of hospitals entitled to a share was increasing more rapidly. Last year the undesignated fund was distributed among 26 hospitals. This year 32 will share in it. Last year the total of free days was 428,659. The present year they will approximate 575,000, about 100,000 being due to the increase in the number of the hospitals in the Association, and the remainder to an enlargement of the work of the older members.

Quinine cost $20.00 per ounce in 1823, and $3.00 in 1853; $3.70 in 1878; while now it costs from 18½ to 24 cents.

The Sum of $5,500 has been subscribed to the Volkmann Memorial Fund.

Every Case of Typhoid Fever is a case of water-poisoning. This is a useful item for the public to keep in mind.

Coffee-Tea.—In coffee the leaves are said to contain 1.26 of theine and the berries only 1.0 per cent., and yet over 110,000,000 men use the berries and only 2,000,000 the leaves of coffee, although 500,000,000 use the leaves of tea. It is suggested that coffee-tea be used as well as the coffee berry.

Lettuce is said to contain a minute amount of hyoscyamine, and this gives to the plant its feeble soporific properties.

At the World's Fair there are to be two special hospitals. One of these is to be under the direction of Dr. Owen, and is to be the official hospital of the Exhibition; the other is to be a model hospital in the Woman's Building. In connection with this model hospital will be the Department of Public Comfort, where couches and beds will be provided for such cases of accident or indisposition as do not need serious medical attention.

Part of the Eastern Michigan Insane Asylum at Pontiac was destroyed by fire on December 26, 1891. Many lives were imperilled, but it is believed that none were lost.

Protection for Railroad Employees.—In his Annual Message to Congress the President says: "I have twice before urgently called the attention of Congress to the necessity of legislation for the protection of the lives of railroad employees, but nothing has yet been done. During the year ending June 30, 1890, 369 brakemen were killed and 7,841 maimed while engaged in coupling cars. The total number of railroad employees killed during the year was 2,451, and the number injured, 22,320. This is a cruel and largely a needless sacrifice. The Government is spending nearly $1,000,000 annually to save the lives of shipwrecked seamen; every steam-vessel is rigidly inspected and required to adopt the most approved safety appliances." He recommends the compulsory introduction of automatic coupling for freight cars.

Gynecological Tinkering.—Dr. Joseph Price writes, in the *American Gynecological Journal*, to show that major gynecological operations are often necessitated by too much minor gynecology. The argument, he says, used for the measures referred to is that they increase the chances of conception. "A comparative study of cases undergoing a prolonged treatment of a radical nature, such as application of the stronger acids to the cervix and the endometrium, the frequent curetting of the uterus, the repeated dilatation of the cervix, will prove that conception is less frequent in these cases than in others where all local applications have been discarded and general treatment used, and where treatment has been especially directed to the careful and gentle correction of mechanical dislocations, resulting in engorgement and congestion or inflammation. My own dispensary work is a constant demonstration of the correctness of this opinion. Since abandoning local applications conceptions have increased more than ten per cent. in the same group of cases in which I used local treatment and tinkering early in my experience. I have so often condemned the sound in gynecological work that it will seem foolish, and will, no doubt, be futile, to do so again. To that class of gynecologists who cling to its use, there is but little use of directing proof. Their own experience is not sufficient for any one but themselves, and they will learn from no one else."

The Diseases of the Kidney were formerly nearly all classed under the head of inflammations. This is not correct. Many inflammatory forms of Bright's disease are now known to be degenerative or simply congestive. The inflammations of the kidney, according to Delafield, are: 1, Acute exudative nephritis; 2, acute diffuse nephritis; 3, chronic diffuse nephritis, with exudation; 4, without exudation; 5, suppurative nephritis; and 6, tubercular nephritis.

The Bichloride of Gold Mixture is said to consist of an aniline-colored compound of strychnia and atropia. To this is added Jamaica dogwood, or codeia, for the opium habitués.

The Medical Profession of Louisville, Ky., is taking steps to enforce the State law against quackery.

A Medical Library is to be Established in Pittsburg, Pa. The managers of the Pittsburg Free Dispensary have granted the use of suitable rooms, and a nucleus for the library is formed by the library of the late Dr. Benham, which has been donated by his widow.

Dr. Henry F. Campbell, of Augusta, Ga., died on December 15, 1891, aged sixty eight. He was born in Savannah, and graduated in medicine at the University of Georgia. He was a surgeon in the Confederate service, and afterward Professor of Anatomy, and later of Surgery, at the New Orleans Medical College. He was President of the American Medical Association in 1885.

The International Congress of Hygiene is to hold its next meeting at Buda-Pesth, which does not seem to be a very good type of a sanitary locality, and will therefore perhaps benefit all the more for holding the Congress. It is announced this week that all the schools are to remain closed till January 6th, on account of the prevalence of infectious diseases. In three weeks no fewer than 319 school children fell ill of scarlet fever, and 31 died; 203 had diphtheria, 74 died.

Vaccination as a Prophylactic against Influenza.—Dr. Goldschmidt (of Madeira) some time ago adduced evidence (*Berlin. klin. Woch.*, November 19, 1890) that vaccination had a prophylactic influence as regards influenza. An epidemic of small-pox broke out in November, 1889, and rapidly extended over the island. In January, 1890, influenza made its appearance, the epidemic reaching its height in February and March, disappearing gradually in May. Just at the time it was becoming severe, revaccination was becoming extensively practised on account of the contemporaneous invasion of small-pox, and it was observed that all successfully revaccinated persons remained exempt from influenza. Goldschmidt observed 210 cases of revaccination, 112 being successful. Out of the 98 without result, only 15 contracted influenza, and even these were very slight cases. In an isolated villa with 26 inmates, of whom 14 were not revaccinated, all the latter were attacked with influenza, in two cases very dangerously; while all those who had been revaccinated remained free. In a recent paper Goldschmidt presents further evidence in support of his view.

The Academy Prizes.—Nineteen prizes, ranging in value from $75 to $1,000, were recently awarded by the Paris Académie de Médecine. Among the more important were the Laborie prize of $1,000 for the best works on surgery. This was divided between Dr. Thiéry ($500) for a work on "Surgical Tuberculosis," and Dr. Delpit and Dr. Delorme. The Academic prize of $2,000, "On the Part taken by Air in the Transmission of Typhoid Fever," was also divided between Drs. Sicard, Delahousse, and Boucher. The Barbier prize of $500 is given to the discoverer of a cure of diseases hitherto supposed incurable. Half of this was given to a veterinary surgeon for a work on "Acute Mammitis." Most of the Meynot prize of $500 was given to Dr. Nocati, of Marseilles, for a work on the "Aqueous Humor." We note that nearly all the prizes were rather freely divided, a practice indicating apparently a low standard of excellence in the competing essays.

Dr. James Risdon Bennett died recently, aged eighty-two years. Dr. Bennett graduated in Edinburgh in 1833, and was afterward appointed Lecturer at Charing Cross Hospital. He became Fellow of the College of Physicians in 1846, and was elected President in 1876. In addition to his connection with St. Thomas's Hospital he was Physician to the City of London Hospital for Diseases of the Chest. He had been a member of the General Medical Council and of the Hospital Sunday Fund Committee. He received the honor of knighthood in 1881.

Dr. Louis Felix Henri Féréol, of Paris, lately died, aged sixty-seven.

The Results of Modern Antiseptic Management of Labor.—Out of 1,340 women delivered in Professor Tarnier's wards during the past academical year, only 14 died, thus giving a mortality of 1 in 95, or 1.04 per cent. Eight years ago the mortality, calculated on the same number of cases, reached 2.50 per cent.; while thirty years ago one parturient out of 11, or nine per cent., died. Better results than Tarnier's can be shown, we venture to say, in some of the hospitals of this city. At the New York Infant Asylum, in 1890, there were 219 births, and no deaths recorded.

Movement of the Bowels per Os.—There are a great many painful and disagreeable things connected with pathological disturbances in human economy; but none could possibly be more exquisitely disagreeable than a systematic reversal of intestinal peristalsis. Such a condition of things, however, is described in *La Médecine Moderne* (*Medical Press*) as having occurred in an epileptic patient of M. Desnos. For two years this unfortunate creature had a movement of the bowels by the mouth only, at about 6 P.M. daily. The event was, of course, in the nature of a stercoraceous vomiting.

The Point of View as to Actinomycosis.—There seems to be a difference of opinion as to whether people ought to eat sarcomata and substances of that nature.

The Illinois Live Stock Commissioners decided that lumpy jaw in cattle is contagious and renders the meat unfit for human food. A convention of cattle-raisers further West, the other day, resolved that lumpy jaw is not contagious and does not render the meat unfit for human food.

Dr. Stefani, of Milan, asserts that a mixture of tartaric acid and bicarbonate of soda acts as a hypnotic.

The Annual World Mortality from Suicide is estimated to be 180,000. Suicide is rare among mountain dwellers, or among those who live in marshy plains.

Dr. Joseph Clarence Tucker died at his home in Oakland, Cal., on December 23, 1891, aged sixty-three. He was a descendant of Dr. Robert Tucker, the first physician who graduated in America, and who was licensed as such by King's College (now Columbia), in this city, in 1751. The deceased, who was born in New York, on taking his medical degree went to California, with the first emigration, in 1849.

Dr. R. E. Warner died in Seymour, Conn., on January 1st, of pneumonia, aged thirty-seven. He was a graduate of the Yale Medical School.

The Night Medical Service of New York died a natural death. The night service of Paris, however, continues, and reports show that over 2,000 calls are made yearly.

The Well-known Surgeon, Professor Léon Tripier, of Lyons, died recently, aged forty-nine.

A National Board of Health.—Senator Harris, Chairman of the Committee on Epidemic Diseases, has introduced a bill in Congress providing for the creation of a National Board of Health, and defining its powers. The board is to be under the control of the Treasury Department, and is to consist of seven members. Three mem-

bers are to be sanitary scientists, and are to be appointed by the President, by and with the consent of the Senate, not more than one to be chosen from any one State. These three members are to receive $5,000 salary each. Three medical officers are to be detailed, one from the Army, Navy, and Marine Hospital service, respectively, to receive no other compensation than their salary, and the seventh member is to be detailed from the Department of Justice, and to be learned in the law—no pay except his salary as judge. The object of the bill is to better enforce the quarantine laws with reference to the introduction of epidemic diseases from foreign parts.

To Increase the Hypnotic Power of Sulphonal.—Dissolve the sulphonal in three-quarters of a cup of hot water, add cold water until the temperature of the water allows it to be drunk, when it may be administered. Its action sets in at once and causes no disturbance.

Dr. Henry O. Mayo, United States Navy, died in this city, December 31, 1891.

The City of London has established a Public Health Department.

New York City's Birth-rate in 1890.—For the first time in many years the reported birth-rate of New York City has exceeded the death-rate.

The Weapons of Modern Warfare.—On December 2, 1891, Professor Billroth delivered a speech in the Austrian Parliament on the probable effects of the new weapons in the next war. *The Lancet* translates the most important passages as follows: "The experience of army surgeons teaches that wounds caused by shells and cannon-balls are very slight compared with those caused by rifle projectiles; that very few wounds are inflicted by artillery, still fewer by cavalry, for cuts and stabs are very rare. About eighty per cent. are due to rifle-fire. The attention of army surgeons must therefore be directed mainly to rifle projectiles. As to the effect of the new projectiles, it is true we have no experience. Some think it will not be so bad; they will shoot in future at so great a distance that the bullets will either not hit at all or seldom, or go too far, and soldiers will confine themselves to manœuvring the enemy out of position, and go in less for slaughter *en masse*. Manœuvring out of position, however, is a thing which has its limits. The tug of war must come at last. Owing to the greater range and propulsive power of the new rifle, its effect will be important, and the bullet, which used to be stopped when it struck a bone, will go through it, and perhaps through two or three more. The range of the new projectile is said to be a kilometre and a half (about fifteen-sixteenths of an English mile). The number of the severely wounded will therefore be much greater. The rapidity of the firing will be still further increased by the circumstance that the smokeless powder will allow the enemy to be better seen. Owing to the greater range of the projectiles, too, the rear hospitals will have to be further back, and the difficulty of transport will be proportionately increased." Professor Billroth then spoke of the effects of the smokeless powder, and pointed out that the storming of fortified points will be possible only with tremendous sacrifices. *Per contra*, several recent cases of gunshot wounds with the new rifles appear to show that the bullets make small, clear wounds that cause no shock, but act like a stab, and if no vital part is struck do little damage.

The Journal of the American Medical Association prints a list of nearly six thousand members. We note that New York heads the list in number of members, and also that New York physicians are the most frequent contributors to its pages. Indeed, New York and Pennsylvania contribute nearly one half of all the original articles. Illinois comes next in the list and stands second in membership.

The World and the Doctors.—"The world refuses to admit that physicians should govern their conduct by the laws of business, however honorably applied. When the physicians of Findlay, O.," says the *Journal of the American Medical Association*, "during an epidemic, raised their fees from the modest sum of one dollar a visit to the still modest and inadequate sum of one dollar and a half a visit, the whole country was notified of their barbarity by the inconsistent people of that town, who but a few short months before had flocked there for purposes of speculation, and who had held farms and 'town' lots at enormous figures because they could, and who had not hesitated to receive such sums for their land as the 'gas boom' brought on, and who took particular pains to close out their deals before the drop came." A recent attempt by the physicians of South Chicago to form a protective association led an attorney to announce the remarkable doctrine that physicians, being licensed by the State, could not withhold their services when demand for them was made. Preposterous!

Supplies for the City Hospitals.—The Commissioners of Charities and Correction have advertised for bids for supplies for Bellevue and the hospitals on Randall's and Blackwell's Islands. Among other things wanted are 4,200 gallons of rye whiskey, 350,000 yards of gauze, 12,000 pounds of absorbent cotton, 6,000 pounds of absorbent lint, 4,000 pounds of carbolic acid, 3,500 ounces of quinine, 125 ounces of morphine, 4,000 pounds of castile soap, 2,500 pounds of castor-oil, 410 gross of prescription bottles, and 1,875 gross of corks.

A Special Hospital for the treatment of skin diseases will soon be opened in St. Petersburg.

The Marine Hospital Service.—There is said to be some commotion at the head-quarters of this service, occasioned by the attempt of the former supervising surgeon to be reinstated in the position he formerly occupied before going to Chicago. The latter city was found not to be as agreeable a place of residence as Washington. The present head of the Marine Hospital Service naturally is not anxious to be deposed to make way for his former superior, and is said to be at work strengthening his defences in order to resist the attack.

The Prix Broca, which is awarded at the École de Medecine every year to the student who has made the greatest advance or discovery in the science of anthropology, has been presented to Dr. Carlier.

Warm Ether as an Anæsthetic.—We learn from the *Independencia Medica*, of Barcelona, that on October 31, 1891, Dr. Giné y Partagás performed an operation for osteoma of the fibula on a woman, in the Hospital de Santa

Cruz, of that city, the anæsthetic used being ether warmed to 31° C., which was administered by Dr. A. Diaz de Liaño, with an apparatus of his own invention. Anæsthesia was rapidly induced, and was kept up for fifty-five minutes without any accident. The temperature of the ether remained at 31° nearly to the end, when it fell to 29 5°. The apparatus, which is called by its inventor an "electro-thermo-etherizer," has since been used in several other cases with equally satisfactory results, anæsthesia having on one occasion been kept up for two hours and a half without any ill effect. Dr. Diaz de Liaño claims that by his method the disadvantages both of cold ether and of chloroform are obviated. Our contemporary promises a full description of the apparatus at an early date.—*British Medical Journal.*

Apomorphine in Fever.—Dr. W. B. Miller reports a case (*British Medical Journal*) showing apparently that apomorphine, dose gr. $\frac{1}{10}$, is an antipyretic.

Billroth on the Position of the Doctor in Society.—In a recent speech before the Austrian Parliament on the bill to establish "Aerztekammern," or a general medical council, Professor Billroth said that he had learned of three classes of public teachers that swayed the populace in morals and culture, whose duties were tolerance, peace, and humanity. The priest has the power of the Church behind him; the advocate the protection of the law, under the authority of State, with the support of his "Chamber;" but the doctor dangles in mid-air, between heaven and earth, with nowhere to rest; his habitation from door to door, with no more protection than any other burgher; no protection beyond individual conversation; who may, at any individual caprice, be injured without any hope of redress. Notwithstanding this, the doctor is entrusted with individual lives, where the simple neglect of inhaling a drug might be fatal, or during the anæsthesia the will of the less scrupulous might be satiated; yet his calling is left without any special professional protection. During the discussion on this bill he had read very disparaging arguments against the establishing of "Aerztekammern," maintaining that the profession had now become discredited and could no more expect to obtain the trust and confidence reposed in it in former years. A number of the profession did not scruple to advocate this assumption, but these were men, he contended, unworthy of the profession, whose motives and assurances were false. On the contrary, there never was a time when the profession stood so high in morality and scientific knowledge. A glance at the region of operative surgery was proof enough for this argument. Science and practice, however, are not necessarily bound together. The patient has his social opinions formed, which must be modified or overcome by the attendant, who is constantly placed between performance and progress. The doctor cannot appeal to his patient on the ground of science, or his practice will soon fail, no matter how scientifically accurate in diagnosis or prognosis. Doubtless our predecessors had more respect in being more positive and better suited for public opinion, where science could hardly be recognized by a third of the profession, while three-fourths of it was conducted on speculation. After detailing the various relationships that existed between the attendant and patient, he pointed out that the modern scientist had one great difficulty to overcome—the fee. The advocate could be on friendly terms with his client, and reckon up the details of his account with accuracy and profit, but this was different with the doctor. The patient called on him, met him and consulted him in the street, or invited him to call at his home, but a detailed reckoning was out of the question, or the doctor is a mercenary fellow, etc. In this direction he thought the "Aerztekammern" would remove a good deal of asperity, where the profession would be protected under a State concession.

Australian Medical Congress.—The Third International Medical Congress, of Australia, will be held at Sydney, in September of this year. Those desiring information concerning the meeting should address Dr. Knaggs, 16 College Street, or Dr. Anderson Stuart, Sydney University, Sydney, N. S. W.

The Death of Dr. Levi Olmstead Wiggins makes a sad break in the ranks of the younger medical men of this city. He had shown such unusual mental ability that a brilliant future seemed in store for him, and he possessed to a remarkable degree those qualities which made him a good friend and a good physician. He entered Yale with the class of 1885 the youngest man in his class, obtaining the highest mark ever given in that college on entrance examinations, and was graduated as the valedictorian. At the College of Physicians and Surgeons of this city he stood second in his class and took the Harsen prize of $200 for general proficiency at examination. During his third year at the medical school he was the assistant of the late Dr. Henry B. Sands. He passed through the regular medical service as a member of the house staff at Roosevelt Hospital and then studied for a year in Vienna and Dublin. While serving in the Rotunda in Dublin he was attacked with double pneumonia, from which he only partially recovered, and returned to this country in the spring of 1891. Since that time he has steadily declined and died suddenly at his home in Newburg, Sunday, December 27, 1891. He was a thoroughly good physician and commanded the respect and affection of all who knew him

Denver Undertakers have for some time been in the habit of burying people whenever they felt inclined without the formality of a permit, but now it is said that the Board of Health has issued very stringent instructions to funeral directors and superintendents of cemeteries. Hereafter the funeral director in charge will be required to present the burial permit to the cemetery officials before any interment will be allowed. It was a Denver undertaker, we believe, who used to display an attractive advertisement with the taking legend, "You kick the bucket, and we do the rest."

Northwestern Medical and Surgical Society.—At the Twenty third Annual Meeting of the Northwestern Medical and Surgical Society of New York, held December 16, 1891, at the Hotel Cambridge, the following officers were elected: *President*, Dr. Edward S. Peck; *Vice-President*, Dr. Charles L. Dana; *Secretary*, Dr. Henry L. Taylor; *Treasurer*, Dr. Frederick Peterson. Several important changes were effected in the constitution and by-laws of this time-honored society.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 3, 1891.

ALFRED L. LOOMIS, M.D. PRESIDENT, IN THE CHAIR.

Increase of Annual Dues. — The question of raising the annual dues from ten to twenty dollars, to meet the increased running expenses of the new building, arose, and Dr. Crampton offered as an amendment that the dues be made fifteen dollars. Dr. Laurence Johnson and others opposed the amendment, saying that the majority of the Council, and the treasurers of the Academy and Board of Trustees, all agreed that a less sum than twenty dollars per member would leave a deficit at the end of the year. Drs. John Irwin and Dessau were in favor of leaving the dues at ten dollars, and of raising the other ten by assessment, as was done last year. The President said that, doubtless, in time the Academy would receive further donations, and it was likely the dues could soon be reduced again to fifteen dollars, or perhaps ten dollars; but at present they could not get along with a less sum than twenty. The original motion recommended by the Council, to raise the dues to twenty dollars, was carried.

Drainage of the Uterus in Chronic Endometritis and Metritis, with or without Salpingitis.—DR. WILLIAM M. POLK read the paper. His remarks, he said, would be less upon the principle of drainage, the correctness of which all would admit, than upon the practical application of it in the class of cases referred to in the title of the paper, those of chronic endometritis and metritis, with or without salpingitis. It might be stated almost as an axiom, that any procedure which could be applied successfully only by one or two operators was open to question. It might be that the plan which he proposed would share the fate of many going before it, be looked upon as the fad of an operator striving for novelty. The consensus of the best opinion, even at the present day, was in favor of the extreme obstinacy of chronic inflammation of the body of the uterus, and some went even so far as to pronounce it, under conditions which were measurably common, incurable. There was very general fear of intra-uterine medication, and it seemed to be a rather prevailing view that even the best methods of treatment altered but little the unfavorable prognosis.

The author would not have dared invade the uterus as a matter of routine, had it not been for the lesson which he had learned in vaginal hysterectomy. It seemed that if one could take out the uterus with comparative immunity, he ought to be able to drain it with absolute safety. All that was necessary was perfect cleanliness.

The conditions to which he had applied the method of treatment which he was about to describe included acute as well as chronic inflammation of the uterus and its appendages, but in the present paper he treated of chronic inflammation only, that which passed under the names chronic endometritis and chronic metritis, with or without associated salpingitis. The type of disease known as endometritis fungosa had been present in quite a fair proportion of the cases, and also in them, when the curetting was thoroughly done preliminary to the draining by gauze, the result had been as good as one could desire. Where any form of flexion existed a permanent result was obtained only after correcting the flexion. Still, its existence did not constitute an objection to the gauze-packing, for here the packing cured the endometritis more quickly than any other means before employed by him; yet the deformity of the uterus was dealt with either at the time of the packing or subsequently by operation, pessary, or stem, as seemed necessary in the individual case.

It was in cases of endometritis or metritis, associated with salpingitis, that this mode of treatment was likely to meet the greatest opposition, for it had long been taught that in the presence of peri-uterine inflammation the interior of the uterus was not to be invaded.

The author favored an attack on the interior of the uterus in chronic endometritis and metritis, because by so doing one could prevent extension of the disease into the sound appendages, and where the tube was affected he might so modify the disease as to limit the damage done. Where but one tube was affected it could be safely left if uterine drainage were resorted to, whereas without such uterine treatment, to leave the healthy tube would be to invite a second laparotomy for its subsequent removal. Where an acute process was at work he tried first to allay it with hot douches, etc., but if it did not yield soon to such methods he proceeded to treat the interior of the uterus. But the question which forced itself upon all minds was, Was the treatment dangerous, would it produce a peritonitis or a salpingitis? He could answer, most certainly, if it were done improperly. But properly done, it would not. In proof of this statement he presented temperature tracings, etc., of over forty cases, which would enable all to judge for themselves of the immediate effect of the treatment. The ultimate results would relate to the permanency of the cure, and on this point he could only say that none of the patients had returned for treatment, and some having remained under observation six months or a year had been practically well. Immediately after the operation there was likely to be a slight elevation of the temperature, continuing twenty-four to forty eight hours, but this was due not to any peritonitis or other serious inflammation, but rather to the surgical result, as was seen in many other operations.

Before describing the method of treatment, Dr. Polk gave a synopsis of some cases illustrating different classes. One was that of a German woman, aged twenty-one, admitted to Bellevue, October 12th, giving a history of pelvic inflammation beginning five months before, coming on after what was undoubtedly an induced abortion. She had been treated at the dispensary for chronic salpingitis during three weeks. That improved. When admitted, the uterus measured four inches and a half; it was sensitive and partially fixed, evidently upon the left side. There was a very sensitive mass in the region of the left broad ligament. A few days later the uterus was curetted and packed with gauze. It was again packed about seven days later, this time the os being so well open that it was not necessary to give a general anæsthetic for its dilatation. Seven days later the canal measured three inches; there was no tenderness, no discharge, and the patient went out cured.

In another case there was disease in one tube, which he removed, leaving the other healthy one, dilated the uterus, packed with gauze, and in a month the patient left the hospital in good condition. He mentioned this case to show that he did not hesitate to attack the interior of the uterus for endometritis, for the purpose of preventing extension of disease to the other tube, one tube having been found diseased and was removed. He had had three or four such cases, and all had done well. If adhesions were found, he broke them up at the same sitting.

The details of the operation pertaining to dilatation of the uterus, curetting, and insertion of gauze, were given, together with particulars of antisepsis. Bichloride solution was used in the vagina and uterus. The operation called for a strip of cheese-cloth of three feet, four thicknesses; a large-sized cervical speculum which was introduced with a plug in it; a speculum, long dressing-forceps, Volsella forceps, a good dilator—he preferred bougie dilators—a sharp curette, a fountain syringe, glass tube, and a general anæsthetic; for in seventy-five per cent. of all cases general anæsthesia was called for, in the remaining twenty-five per cent., mostly cases of subinvolution, the os being sufficiently dilated to call for only a local anæsthetic.

The vulva, vagina, and cervical canal were as thor-

oughly cleansed as if the intention were to take out the uterus. After dilating the cervix so that the speculum could be introduced, the uterus was irrigated with bichloride solution, the speculum insuring a good outflow. Then the walls were gone over thoroughly with the sharp curette, the energy of the attack being gauged by the density of the walls, as shown by their resistance. After this, repeat the washing with bichloride solution. The gauze, which had been since the first irrigation standing in a solution of bichloride, 1 to 500, was now put in simple hot water and squeezed dry, and inserted with the tampon screw into the uterine cavity, the end of the strip being coiled up against the cervix in the vagina, further supported by another tampon in the vagina. It was allowed to remain in six days, and then, if it had not been expelled it was removed, and a cleansing douche was given. The seventh day the patient could get up, and the length of time she remained from her work, unless the tubes were involved, never exceeded two weeks. Rarely was a second treatment called for.

Dr. W. T. Lusk, being invited to open the discussion, said that he had had no experience with the method described by Dr. Polk, but that he meant to give it a trial. Of course, he had been for many years an ardent advocate of the principle of drainage. Anyone who had seen the wonderful results of even simple dilatation of the cervix in cases of catarrh of the cervix and interior of the uterus, would be prepared to believe at once in the success of the method practised by the author. When inflammation once developed within the uterus it could not be cured as long as the lining membrane was constantly bathed in unhealthy secretions. The first necessity was to cleanse the canal and keep it clean, and to do that dilatation was necessary. As previously stated, he had seen excellent results from dilatation, curetting, and application of compound tincture of iodine in the uterus. Indeed, from such treatment he had seen many cases of tubal disease get well, which led him to think that many cases of tubal disease were due to simple damming up of secretions at the cervix. Many years ago a physician from Brooklyn went to a number of medical journals to have printed an article describing the use of a steel dilator, but it was rejected, and he came to Dr. Lusk, who was led to write an article on the subject of forcible dilatation of the cervix, which was printed in the *New York Medical Journal*, but, he believed, met with general condemnation. He often wondered why a procedure which then was said so commonly to produce metritis, peritonitis, etc., could now be practised with as little risk as attended filling a carious tooth.

In subacute conditions of the uterine cavity he had practised a method differing somewhat from Dr. Polk's, with most astonishing results, seeing patients who formerly would have been given up as practically moribund, begin to revive and improve immediately after cleansing the uterus.

Dr. C. C. Lee had practised curetting and drainage of the uterus, but in cases where he had removed submucous fibroids, or where the patient had had an abortion, etc., and in a manner somewhat different from that described in the paper. On looking over his records he had also found over forty cases of endometritis so treated the past three or four years. He divulsed, and used all the antiseptic precautions named by Dr. Polk, except that he injected simply hot water instead of bichloride into the uterus. Instead of inserting gauze, he put in a glass tube for a drain, leaving it in ten days.

Dr. W. Gill Wylie said that dilatation and drainage of the uterus, if not by gauze, yet by some other means, had been taught and practised at least twice a week the past eight years at the Polyclinic. Thus, uterine drainage was certainly known to more than two thousand of the younger men scattered throughout the States. Essentially the same speculum shown by the author had been used at the Woman's Hospital about twenty years ago, but this one was too large to enter the canal except in cases of subinvolution, and in them simple curetting and irrigation would answer without special means for drainage. But in cases of imperfect development of the uterus, with dysmenorrhœa, sterility, endometritis, etc., the internal os could not be dilated sufficiently to let the speculum enter, or for the introduction of gauze. The statement made by some authors that the internal os could be dilated an inch and a half or an inch and a quarter was erroneous; it would tear first. In such cases of chronic endometritis he had tried various instruments for drainage, but had put all aside for the hard-rubber tube with a slight bulb on the upper end to hold it in place, and which, placed in hot water, could be bent into the desired shape. If there were any acute symptoms, as fever, in cases of uterine disease complicated with tubal enlargement, the method should not be practised. Again, he would not use the curette in a large, soft uterus until he had reduced it in size by preliminary treatment. It was easy to pass the curette through the walls of the uterus in such cases. Thus he would advocate drainage, but in a modified way. In some cases the curetting, cleansing, and drainage would prove only of temporary benefit, why he could not say.

Dr. George M. Edebohls resorted to divulsion and thorough curetting without drainage, and was thus enabled to cure cases of endometritis without salpingitis, as indicated by enlargement of the tubes or sensitiveness of them on palpation. But where there was associated salpingitis, something more would be called for; that is, the curetting should be followed by drainage, and of the various modes of draining which had been proposed he thought the one described by Dr. Polk would prove the most thorough. He thought there was no danger in invading the uterine cavity if one observed perfect asepsis and gave free exit to the secretions subsequently; and when there was disease of the appendages, or even pyosalpinx, the operation was not serious provided undue mechanical insult were not offered in pulling down the uterus, etc.

He had practised drainage of the uterus in three cases of pyosalpinx, in which the tubes would empty themselves through the uterus and fill again from time to time, being convinced that the obstruction was at the cervix and not in the uterine end of the tube; he introduced Outerbridge's speculum inside of the internal os and left it in a month or two. The girls had had no further attacks, the last one having been treated as long ago as a year. He would not have dared resort to the use of this speculum had not the cavity already been secreting pus.

Pre-eminently Surgical.—Dr. Florian Krug regarded the treatment described in the paper as pre-eminently surgical, and therefore sound and sensible. Gynecology was too much handicapped by rules of treatment laid down in the pre-antiseptic period. In endometritis, the uterine cavity should be looked upon as an abscess-cavity, and be treated in the same way. It had been his custom for three years past to dilate the cervix, curette the interior of the uterus, and introduce iodoform gauze in his practice at the German Hospital, taking due antiseptic precautions by cleansing the vagina and uterus. He thought it was well that a warning should be sounded to those who were in the habit of applying nitric acid, strong currents of electricity, and all sorts of caustics to the interior of uterus without having made thorough dilatation and given all chance of egress of secretions.

Endometritis not Demonstrable Post Mortem.—Dr. T. A. Emmet said that twenty-five or thirty years ago he treated cases of subinvolution and endometritis by dilating the cervix with tents, then throwing in hot water until the uterus contracted down again, and in a large number of cases the effects for a time were admirable. True, he lost a patient now and then, he did not know why. Gradually he gave up this practice because his patients did not remain cured, and also because patients with subinvolution could almost always be cured by an operation on the cervix, which usually in them was lacerated. He thought, however, that the treatment recommended

in the paper had a field of usefulness in cases where the tube was discharging pus into the uterus. He had been trying to apply the general principle in such cases the last year or two, and although he had not met with much success, yet he thought it deserved a fair trial. He believed that in some cases the pyo salpinx was cured by the pus escaping through the uterus and the walls of the tube becoming adherent to one another, in the same way that any abscess-cavity disappeared.

As to thus treating endometritis and chronic metritis, he would be very glad if someone would tell him what those diseases were, or rather demonstrate them at the dead house. He had been unable to find any such condition at autopsy, although he had often looked for it. Nor could he understand how an inflammation of the lining membrane above the internal os could exist in a woman who was menstruating, for there was no true mucous membrane above that point. Unless an injury had taken place above the internal os at parturition, or there were a new-growth, he did not believe a diseased condition could exist there any length of time which nature would not cure. He never any more made an application or even put the sound into the uterus, unless there were a new-growth or some injury caused by parturition. He could not imagine an unmarried woman having a condition of uterus above the internal os, unless there were a new-growth, which could require direct treatment.

Where a hypersecretion existed it indicated a new-growth, and was a symptom, not a disease. Results might be obtained from making applications in so-called endometritis to the cavity of the uterus, but better results would be obtained if the applications were made only within the vagina. The disease was not above the internal os. In subinvolution the treatment was hardly worth applying; the symptoms would return unless other measures were resorted to.

Dr. H. J. Garrigues objected to the use of bichloride of mercury, and recommended one per cent. creoline, which was antiseptic, not poisonous, and had further advantages in being slippery and somewhat hæmostatic. He also showed a forceps which could be introduced up to the fundus, and took the place of a cervical speculum when one did not wish to dilate. Electricity could be used without dilating the cervix and do no harm, for the reason that it was itself an antiseptic.

Dr. Polk closed the discussion. He did not doubt but what creoline was just as good an antiseptic as bichloride, but the latter applied to so small a surface could not cause symptoms of poisoning. Regarding the use of the term endometritis, he employed it in the sense it was used in the text-books. Replying to Dr. Wylie, he said he claimed no novelty in the cervical speculum employed, and he supposed even Dr. Wylie would not claim priority as to the principle involved in the mechanism of a speculum. Regarding his charge that the speculum and gauze could not be introduced except where there was subinvolution, he did not doubt that from Dr. Wylie's stand-point they could not; but if Dr. Wylie would come to his ward he would demonstrate to him that from a clinical stand-point they certainly could. And as to the principle of drainage having been first taught at the Polyclinic, that could not be, for this principle was as old as the speakers themselves.

Dr. Wylie: I was referring to the practice.

Dr. Polk: And you say you have been trying to get the profession to adopt your mode of applying drainage for fourteen years? Now try mine, and if you do not accomplish anything at the end of three, I will give you the right to denounce it heartily. [Laughter.]

The International Congress.—It was at first decided to hold the Rome Congress in the spring of 1893, about Easter time, but it is now thought that September will be the time appointed. If the expected row, for which the nations of Europe are in training, comes off, the Congress will doubtless be postponed to a more propitious season.

Correspondence.

THE EARLY STRUGGLE—"NOT AN EXCEPTIONAL CASE."

To the Editor of the Medical Record.

Sir: The editorial in the Medical Record for December 19, 1891, under the above caption, carried the writer back to a period early in the last decade, when five chums assembled about the boarding-house table and discussed plans for life-work. Hopeful in the possession of beautiful diplomas, with visions of a row of broughams drawn up in line before the office-door, and with the words of the graduation-day orator still ringing in our large and willing ears, we certainly were entitled to fine plans. B, C, and the writer decided to work for hospital appointments, but A and D thought it best to go at once to their home towns and begin practice with their respective preceptors. B, C, and the writer were successful in the hospital examinations and all received appointments. Two years passed. D found that his preceptor was a friend while the prestige of having him as a student lasted, but having become something of a rival on graduation, matters were altogether different. At the end of two years he was disgusted at the slow, up-hill work among the poor class of patients in town, who were the only ones that his older competitors did not get, and being a bright active fellow he came to New York again, and engaged in business as a speculator in Wall Street, where he could at least have some fun and excitement in making a failure. A, by this time had found that he was on the way to become an excellent country practitioner, who at the end of a long and tedious experience would be able to do a great many kinds of things for his patients, but who could never do any one thing well—not from lack of ability, to be sure, but from lack of opportunity to work up special medical subjects thoroughly. This did not suit his disposition, for he was a scientist by nature and by training, so he entered the army and there found opportunity to do work in his scholarly way.

C, after graduation from hospital went West and spent about three years in various towns, trying to find a place where there was less competition than in New York, but being unsuccessful in this search he returned and died just as he was gaining a decent foothold here.

B, having finished his hospital course, began professional life in the office of an older practitioner in New York who could turn over to him the poorer part of his overflow. B is a splendid fellow, of everlastingly genial and joyous disposition in the face of all obstacles, and with a constitution that would shame a locomotive. He gleaned among the poor patients assiduously, staying up all night perhaps with a patient who could pay him thirty-four cents for services, and walking six miles to save car fare. Now in this new decade he has a very large and profitable general practice on Murray Hill, and not one of his host of friends would grudge him a cent or a patient in his collection.

The writer, after completing his hospital training in New York, went to Europe for the purpose of working up special subjects, for a general practice, and upon his return, when ready for work, found that he had spent about ten years of time and about twelve thousand dollars in money in his medical preparation. He could have had money from paternal sources, but pride induced him to deprive himself of any important aid from that quarter, and to depend upon himself. He had no friends in New York except a small handful of struggling young medical chums like himself, and a few older boarding-house acquaintances. All that he wanted was a whole lot of the sick folks that he was prepared to treat, but they didn't come very fast. The records of his first year's income are lost, but it amounted to a little less than five hundred dollars. In the second year he made eight hundred and forty dollars (collected). Third year, fourteen hundred and ninety dollars (collected). Fourth year,

twenty-three hundred and eleven dollars (collected), and so on in this progressive ratio until the present time when his business is upon a sound footing. He found that people would not trust him with "good" cases while he was doing all sorts of work, so he gradually gave up general practice; then ophthalmological and orthopedic work that he had put a great deal of time and money upon; and he finally is happy in special work, with the backing of a circle of professional friends upon whom he can depend. He encountered but three obstacles to success: 1st. Youthfulness. 2d. Being of a sensitive and retiring disposition he found that this would defeat him in New York, and the forced bold stand that he took led him into a few mistakes that would have been easily avoided with the smooth policy that comes of riper professional experience. 3d. He has followed very closely a system of gentlemanly ethics in dealing with rivals, and this, which resulted from home training, has cost him many a patient and many a dollar, for the said rivals have taken advantage of the trait with the regularity of clock work, and it is only the comfort of an easy conscience that makes compensation.

Perhaps there is a lesson and a little more hope in this simple tale than was given the young medical man in the editorial which called out the writer.

PATULA.

NEW YORK, December 22, 1891.

MEDICAL EDUCATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Nothing in the pages of your admirable journal of late has interested me more than the recent address of Dr. Stephen Smith on the "Art of Teaching Medicine," and the letter of Dr. W. A. Pusey on the same subject.

The remarkably rapid growth and prosperity of Post-Graduate schools, the popular demand for a longer period of undergraduate study, and the universal use of quiz compends, are signs of the times and have no uncertain sound. They are indisputable evidences that something is wrong—either that the time is too short, that the system of instruction does not make the best use of it, or that the intelligence of medical students is on the decline. The first and last of these conclusions we all know are untrue, so that the second naturally concerns us most. The advances in the art of teaching medicine have not kept abreast of the marvellous advance in all its branches.

Reading and studying are two very different things, and didactic lectures are prone to develop the former at the expense of the latter. The year formerly spent in reading medicine in a "doctor's office" before going to college has proved to be a waste of time, and so, too, the first-course student reads in a desultory sort of way, when studies and examinations would impress on his mind, more forcibly than didactic lectures, the first principles of our art.

Now, if, as Dr. Smith suggests, this first year was passed under competent instructors, whose duty should be to fix regular lessons for daily recitation, the practical results would be better. Having attended college a good deal myself, and lately as a teacher, I have always observed what a large proportion neither know how nor what to study. They have either not had a good general education, or from force of circumstances have lost the habit of studying and thinking at the same time.

The scheme is practicable, for in all large cities there are numbers of young men who have an abundance of time, and would be willing and able to teach in this simple way, which to the more experienced and learned professor would be arduous and uninteresting.

There is no one branch in which this way of teaching is more important than in anatomy. Few students can be made to appreciate the truth that anatomy is the foundation of all medical knowledge, or that it will be of incalculable benefit to them in their future studies and practice, until in after-life their ignorance of it and the value of it is forcibly demonstrated by some misadventure.

The appetite for food and the thirst for knowledge differ so that one is normal and the other almost abnormal in the majority of us. Appreciating this fact, I have introduced the recitation system, somewhat modified, into the dissecting room at the Medical College of the State of South Carolina, and we hold periodical practical examinations over the dissected subject which all students are obliged to stand. This plan with first-year students has worked admirably, for by this system they are able to appreciate and understand such didactic lectures as may be given later in the course.

The same plan would no doubt work with a great advantage in the other elementary branches.

The whole country is urgently demanding a longer period of study for the degree of M.D. with license to practise, and this has certainly become necessary, for it takes more than one or two years to become familiar with all the modern branches of practical medicine. But this element, time, can, I believe, be materially reduced by better methods of teaching, and a change in the present mode of instruction such as is advocated by Dr. Smith seems eminently advisable.

EDWARD F. PARKER, M.D.

70 HASELL STREET, CHARLESTON, S. C.

PLACENTA RETAINED FOUR MONTHS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Noticing in the MEDICAL RECORD of November 7, 1891, a case of retained placenta of twenty-two days' duration, reported by Dr. Lamadrid, of Brooklyn, I am led to report a similar one.

March 25, 1888, I prescribed for Mrs. B——, aged thirty-nine, for a threatened miscarriage. She was the mother of five children, and had one miscarriage in 1884, to which I will refer later. March 27th, in spite of all precautions, she was delivered of a two months' fœtus, without medical attendance. Upon visiting her the next day she informed me that the placenta had not been passed. She was not flowing, and her symptoms were favorable. I plugged the vagina, removing the tampon the next day, but the placenta remained. Daily for ten days I visited her, expecting and prepared to remove the placenta should symptoms suggestive of complications appear. She, however, made a satisfactory recovery without my further interference. I dismissed myself from daily attendance, fully explaining to her the state of affairs.

During the first month hemorrhages occurred; after this menstruation became regular. She seemed as well as usual, did her own housework, and walked long distances. She was under my casual observation during this time. July 27th, or just four months after the miscarriage, the placenta came away intact. The patient brought it to my office. It was in a normal condition, and after hardening it in alcohol I prepared sections for the microscope, which I have preserved.

Some may criticise my method in not removing the placenta at the first visit, but I had an experience with this same patient in July, 1884, which I wished never to repeat. It was a miscarriage at four months, with placenta retained. Immediate removal was attempted, but only after an ordeal most trying to both patient and physician was it effected. Aside from any desire to save my patient from a repetition of her former agony, my ideas of the methods of removing placentæ, and the necessity therefor, had altered. My present custom in all cases of abortion, with retention, is to plug the vagina, packing well up against the cervix. This reduces the danger of post-partum hemorrhage, and the pressure of the mass against the cervix induces expulsive pains. I leave the patient with perfect confidence, and on removing the tampon the next

day, almost invariably find the entire after-birth lying behind it in the vagina. In this case the failure of the above precaution probably was attributable to the fact that the tampon was inserted eighteen hours after delivery of the fœtus. The opportunity of utilizing and seconding nature's expulsive pains, which are apt to follow immediately on delivery of the fœtus, was thus lost. The placenta of full-term pregnancy is a very different affair, it seems to me, from the placenta of miscarriage. Should I leave a patient after delivery at full term without the complete removal of the secundines, I would deem myself guilty of malpractice; whereas with an abortion, after a moderate use of Cordé's method, and failure therefrom, I invariably tampon and go away.

Hemorrhage or symptoms of septic absorption would compel me to use as prompt and energetic measures as at full-term pregnancy. But I have never had a patient who would come under either of the two classes mentioned. Granted that the placenta is completely adhe rent, and the blood-vessel connection uninterfered with, you have a piece of living tissue in said placenta. It is nourished, and may remain for some months and be passed free from any odor. Or it may remain an indefinite period, shrivel up, undergo retrograde metamorphosis, and be found even at the death of the woman.

In volume ii., pages 333 and 335 of the "Cyclopædia of Obstetrics and Gynecology," edited by Charpentier, and translated by Dr. Grandin, the following cases are quoted: "Schöller has noted retention for 11 weeks; Metz for 2½ months; Prost, 103 days; Flasse, 15 weeks; and Reichmann, 13 weeks." The placenta in all these cases came away odorless and without having caused disturbance.

Hecking reports a case where the placental remnant was passed at the end of four and a half months, and only after many profuse hemorrhages which compromised life.

On the other hand, Kilian, Böhmer, Sandifort, Vallisnieri, Morgagni, Van Swieten, Camerarius, Dedek, and Niemann have recorded cases where foreign bodies containing fœtal débris have been found after death in the uterus of women of the age of seventy-five, eighty, and ninety.

NELSON G. RICHMOND, M.D.

FREDONIA, N. Y.

COCKLE-BURS IN THE LARYNX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of November 28, 1891, Professor Francis L. Parker, of Charleston, S. C., reports four cases of this accident that had come under his care, and refers to two others that were reported by Dr. Pendleton, of Hartford, Ky., and states that these are the only cases he had ever seen or heard of.

In the *St. Louis Courier of Medicine* for February, 1887, was a valuable contribution upon the subject by Dr. S. T. Armstrong, of Memphis, Tenn., in which he reported a case where the bur had been in the larynx for six days, which was relieved by tracheotomy.

Dr. Armstrong then refers to the different modes of treatment, viz: 1. Removal by forceps or other similar means. 2. Removal by tracheotomy. 3. Letting the bur remain *in situ*, with trust in the *vis medicatrix naturæ*.

As an illustration of the first the following reported cases are briefly referred to:

1. Dr. L. A. Deugas, in the case of a negro boy who swallowed a cockle-bur, found difficulty in removing it, because the movements of the larynx prevented the seizure of the bur, which could be felt with the fingers; passed forceps along his finger and removed the bur.[1]

2. Dr. W. C. Glascow removed a cockle-bur by the Schrotter Turck forceps, and also records a case wherein these failed, and subsequently tracheotomy failed; and eventually the bur was removed by a curved forceps.[2]

3. Dr. Max Thorner removed a cockle-bur, located between the vocal cords, after failure with the Schrotter forceps, by the sponge instrument of Voltolini.[1]

4. Dr. D. B. Crowley, who could feel with his finger the cockle-bur in the larynx of a negro boy, having no instruments at hand, wrapped his index-finger with cotton, passed it into the throat by a rotary motion, entangled the spicules of the bur, and so removed it.[2]

The author then refers to a paper by Dr. J. R. Weist upon "Foreign Bodies in the Air Passages,"[3] in which paper he says Dr. Weist records twenty-six cases of cockle-bur without operation, of which nineteen recovered and seven died; while in eleven cases operated upon all recovered. He then gives three other cases of successful laryngotomy, by Drs. Van Note,[4] W. S. Rose,[5] and C. W. Jordan.[6]

And furthermore, if Dr. Parker will refer to page 175 of *The Medical Mirror*, 1890, he will see where I reported two cases of cockle-bur, one in the trachea, in a lad eleven years of age, which was coughed up on the sixth day; and one in which the bur was behind the faucial pillars; tracheotomy was performed by an inexperienced physician, who thought the bur was in the trachea, the result being immediate death.

In addition to these reported cases I have seen an infant, two months old, who had a cockle-bur in its throat for two days and nights, which prevented its nursing or swallowing any but the smallest quantities of fluid. The bur could be felt with the finger, and while I was trying to seize it with forceps, it slipped down the œsophagus, and was passed from the rectum on the second day. The child did well. This was on March 15, 1876.

We have, therefore, forty-six or seven cases of cockle-bur on record, above the six that Professor Parker gives us.

Respectfully,

CHEVES BEVILL, M.D.

WINFIELD, ARK., December 3, 1891.

ALCOHOLISM AND MENTAL PARALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The following bit of personal history, which seems to throw some light on the subject of the responsibility of persons while in a state of alcoholic intoxication, is worthy of attention. The source is entirely trustworthy, the gentleman being well known to me, and it is with his consent that I offer it for publication.

I would also state that the writer of the sketch was, and has been since, a man of the most temperate habits.

DWIGHT L. HUBBARD, M.D.

344 WEST THIRTY-THIRD STREET.

"**A Quart of Champagne.**—In 1862, after the Army of the Potomac returned from the Peninsula, all of it moved to the front to take part in the battle of Antietam except the Third Corps, to which I was attached. That corps was camped near Alexandria, around Fairfax Seminary. In the campaign of the Peninsula my battery was much reduced, and while camped near Fairfax Seminary I received a large detachment of recruits. I then had four Napoleon guns, and the men received made my battery strong enough to increase the equipment to six guns. Accordingly I made requisition for two Napoleon guns and equipment, and for the horses required. The requisition for ordnance stores required to be approved by several officers. First by Captain Webber, the Chief of Artillery of the Third Corps, and commanding Battery H, First United States Artillery; next by General Sickles, commanding the Third Corps; then by the Chief of United States Artillery, at that time General Howe, in Washington; next by the Post Ordnance Officer at Washington, Captain Harris; then taken to the Ordnance

Bureau, in the Winder Building, where the requisition would be copied and an order given on the arsenal for the ordnance stores. This routine I knew perfectly, having gone through it many times.

"Upon the day I went to Washington to have the requisition approved and get the order for the ordnance, I had the requisition approved by the Chief of Artillery of the Corps and by General Sickles; Lieutenant Dimmick, of Battery H, First United States Artillery, accompanied me to Washington. As usual, we rode over on horseback, and having put up our horses we went to Gautier's restaurant and called for dinner. We ate our dinner and with it drank two quart bottles of champagne, that is, one quart each. At sunset we rode back to camp, getting there at dark. My recollection of all that occurred after the dinner is distinct, and subsequent events fixed it in my mind. Having finished the dinner, I went to General Howe and had the requisition approved; then to Captain Harris, who approved it; then to the Ordnance Office, to General Dyer, who ordered the copy made, and secured the order for the stores; then I went to the arsenal, presented the order, and was told to bring the horses on the following Wednesday, when the stores would be ready. According to custom the order was filled. This was a half-day's work, and occupied all the time between the dinner and the time to return to camp. Of all these things my recollection was, and is, perfect. The facts appear to have been different, and the wine must have been the cause.

"On the following Wednesday, with the necessary men and horses for a section of guns, I went to the Arsenal for the stores, and called for the order. I should have said before that I knew every officer in the routine of approval of the requisition personally and quite well. The officer in charge looked over his list of orders and did not find it. I said it was there, and told him what kind of paper it was made out on, white with a blue tinge, that I recollected the paper perfectly. He ordered the search made again, but with no better success, and asked on what day I left the order. I replied on Friday. He said he was in all that day and did not recollect seeing me. I told him I was there, saw him, and talked with him, but as it was late I left soon. He said he could not account for it, as he could have given me the equipment as well on Saturday or Monday as on Wednesday. I thought he was in error and had mislaid the order, but I could not get the equipment without the order, and leaving the men and horses at the Arsenal I returned to the Winder Building, told General Dyer that they had mislaid the order at the Arsenal, and asked that another be made from the requisition. He directed a clerk to get the requisition, but it was not to be found. I insisted that I had taken it there, and had waited for the order to be made, and had taken it to the Arsenal. Another search was made with like results. General Dyer said he did not recollect seeing me Friday. Still there was no doubt in my mind, as my recollection was perfect. I went to Captain Harris's office and asked for the record. He examined his books and found no record of it, nor did he remember of my being there on Friday. Still I told him I was correct, and he again examined his books, but found no entry. I then went to General Howe's office and asked for a memorandum of the requisition. He examined his books and found none. I spoke of being there on Friday, and he did not remember it. To this time I had not once thought of the explanation. I was confident of every step I had taken, and could only think that each officer was in error. Meanwhile, during the entire day, my men and horses had been standing at the Arsenal.

"In riding from General Howe's office to the Arsenal the truth first came to me that I had been drunk from the wine, and the day's work was altogether one of imagination. Knowing the routine well, my mind had assumed the doing of the work, but it had not been done. I then tried to unravel the mystery in my own mind. I felt in my pockets for the requisitions, which if I had not used on Friday I was so confident of having. I had not even attempted to look at these papers during the day—but did not find them, nor did I ever find them or know what became of them. I then examined my pocket-book to see if I had lost any money, which I had not noticed. I found I had not. I had had no use for money, and what I took to Washington on Friday I had there on Wednesday, so I was sure I had not been on any carouse or been robbed. I attempted to account for my time between the dinner and the time I met Dimmick by appointment made after the dinner, and which I kept, to go to camp together. But no light came. I could account for every minute of the time in my own mind, but it was the routine with the requisition. But now I knew that I had not done that work. No other light came to me then, and never has to this day. I found the men and horses at the Arsenal, then near night. I gave them only the brief military information that there was an irregularity in the requisition and took them back to camp.

"I never at any time had been intoxicated, and then had no recollection of feeling any symptoms of it at the time I drank the wine. As soon as occasion offered I made such inquiries of Lieutenant Dimmick as would give me the information I needed to satisfy my mind about that Friday afternoon. He saw no indications of intoxication, but it may be assumed that he was also more or less intoxicated, but I do not think he was beyond a full appreciation of everything that passed. His recollection agreed with my own as to making the appointment to meet at a certain hour to return to camp together. This appointment was made after dinner, was kept to the minute, and we returned together. I did not remain at Gautier's restaurant, but went out with Dimmick, and together we went to the stable and got out our horses, he riding off one way and I another. At the appointed hour we came together again and rode to camp. After the attempt on Wednesday to get the guns, and failing, I made out another requisition, and, of course, got the approvals without drinking wine in the intervals between the different officers approving it.

"What became of that half-day is a great mystery to me. I have thought of it many times and followed it through in all I could remember. Sleep would be the most natural explanation, but where could I have slept! I got my horse with Dimmick when he got his, therefore, I could not have been in the restaurant. I would not have been permitted to sleep in any irregular place, for Washington was patrolled every hour in every part. My clothing showed no indication of having been lain on, and if I called at any officer's quarters and slept the effects of the wine off, I never heard it alluded to after. I did not go to a hotel, or I should have missed money enough from my pocket-book to have at least paid the bill. There is but one solution that I could ever think of, and that was that I went to sleep or became oblivious on horseback, and having a good horse and being a most excellent rider I went from place to place in so regular a movement that the patrol did not even discover that I was not in perfect control of myself. This may have been so, as I had and have since frequently slept on horseback while marching with my command. The afternoon having worn away, I recovered myself, and finding by my watch that it was time to meet Lieutenant Dimmick, I did so as agreed upon. But even this solution is the merest supposition, as I could never in the most remote sense solve the mystery of that afternoon and what I did while under the influence of the wine.

"Lieutenant Dimmick was killed by my side at Chancellorsville, May 2, 1863."

The above memoranda was written in 1865. A gentleman of prominence and wide experience having read the above statement made this memorandum on it. "It is certainly an interesting experience, and it illustrates, as in many other ways I have seen illustrated, how it is possi-

ble for men in courts of law to swear to things that never occurred, with perfect honesty and with the most positive assurance of certainty."

ON THE ADHESION OF THE URETER TO THE PERITONEUM.

To the Editor of the Medical Record.

Sir: Dr. Cabot, of Boston, in his interesting article on the anatomy and surgery of the ureter, just published in the *American Journal of the Medical Sciences* for January, 1892, in which he reports cases of his own and of others where a calculus impacted in the ureter has been removed by surgical interference, makes a statement that is somewhat astray. When speaking of the difficulty of recognizing the ureter in the living subject, during an extra-peritoneal operation, he says that "there is a relation of the ureter to the peritoneum which I cannot find mentioned in any description of its anatomy, a knowledge of which will greatly simplify this search. This is the fact that the ureter is adherent to the peritoneum, and always separates with the peritoneum as it is stripped up from the parts behind."

This is doing some injustice to the many excellent works on operative surgery which can be found on the shelves of every working surgeon. In the "Operations in the Dead Body," by I. Smith, for instance, there will be found under the caption of "Ligatures of the Common Iliac Artery," the words: "Little thought need be bestowed during the operation on the spermatic vessels and ureter, as they generally rise with the peritoneal sac, and adhering to its under surface are scarcely observed." In Jacobson's "Operative Surgery," p. 609, the same fact is stated, and similarly it is contained in the works on this subject of Bryant (J. D.), Bergmann, and Rochs, and in many others that might be cited. This adhesion was taught by the late Professor Sabine, and I learned it myself from Dr. Gurdon Buck, of the New York Hospital, when I was an interne in that institution. Dr. Cabot's investigations have led him, in this new field of operative work, to so many valuable suggestions, that he will, I trust, pardon the correction that I venture to make.

Yours most truly,

R. F. Weir, M.D.

A PHYSIOLOGICAL METHOD OF ARRESTING HEMORRHAGE.

To the Editor of the Medical Record.

Sir: A most able and thoughtful article in the Medical Record of January 2, 1892, written by Dr. Dawbarn, upon "Medical Hemorrhages, Treated by Saline Infusions, Surgically Administered," suggests to the writer the propriety of presenting to the profession a physiological measure which he has never known to fail in the subjection of hemorrhage.

This is attained by acting upon the nervous centres in such a way as to cause an increase of nervous force, which will expend itself upon the terminal ends of the nerves supplied to the coats of the blood-vessels in the bleeding area.

The idea and effective carrying out of sequestration or retirement, so to speak, of the blood into the limbs, by applying pressure around the four extremities close to the body, is scientific and excellent, for it naturally depletes the hemorrhagic area to a great extent. The injection also of a hot saline solution into the arterial circulation, after great loss of blood has taken place, to supply a volume of fluid to float the remaining red blood-corpuscles throughout the body, thus enabling them to perform their proper functions, as well as forming a medium for their rapid renewal, is sound and logical in theory, and evidently works well in practice. Yet, if the hemorrhage can be rapidly and perfectly controlled in post-partum cases, without the use of internal remedies or local abdominal applications, or injections into the womb, but by apparently a simple, yet in reality a most powerful, agent applied over the ganglia supplying nerves to the uterine arteries; then we have the most easily applied, the most effective, and the least harmful practice in such conditions.

Firstly, it checks the hemorrhage rapidly, and so prevents undue loss of blood, and thus obviates the terrible consequences of such loss at so important a time.

Secondly, directly the hemorrhage is checked, the patient becomes comfortable, the womb contracts, and the pulse in the wrists and temples full and regular, demonstrating an even distribution of the circulation in all parts of the body.

The method referred to is the application of heat over the dorso lumbar sympathetic ganglia, in a double-columned Chapman hot-water bag. The water should be 120° F. The bag should be filled and placed over the spine. The bottom of the bag should not be lower than that portion of the lumbar region directly opposite the crests of the ilii, and extend straight upward; the spinous processes fitting in between the columns of the bag.

The explanation of the action of this treatment is, that the heat acts directly upon the sympathetic ganglia beneath it, causing the arteries of the ganglia to expand, thus, by increased nutrition of the central cells, augmenting the function of these cells, which now issue stronger nervous currents than before to the arterial coats of the vessels in the uterus, causing them to contract normally, and so checking the hemorrhage; but this is not all, for the more powerful nervous action of the sympathetics is carried to the motor area of lumbar enlargement of the spinal cord, inducing a hyperæmia in these cells, and therefore an impetus is given through the direct motor nerves to uterine contraction. In proof of the power one irritated nervous centre has to transfer irritation to another nervous centre Ferrier says, page 81:

"It seems to me that the phenomena of electrical irritation of the corpora quadrigemina are mainly of a reflex nature, and depend upon the transference of irritation of sensory centres to motor centres and tracts." All know how one hand placed in cold water will cool the opposite one, and numerous corroborative instances might be given. It is possible that the heat over the sympathetic ganglia may act upon them through the sensory nerves of the skin, but after eleven years almost of experience in this system, I am myself convinced that the effect produced upon the centres is direct. Dr. Chapman, of Paris, says in his work on "Functional Diseases of Women," page 61:

"Flooding, when the womb fails to contract after expelling its contents, and indeed uterine hemorrhage from all causes, will probably be restrained or stopped most effectually, and certainly most agreeably, if at all, by the application of heat over the lumbar region, on each side of the spinal column. I have given evidence sufficiently decisive of the remedial power of heat in menorrhagia, and in soothing the patient meanwhile, to assure obstetricians that they may safely, and probably successfully, test the efficacy of this agent, applied as suggested, when they are called upon to prescribe in cases where health or even life is imperilled by loss of blood from the womb."

In conclusion I would say that I have myself stopped hemorrhage from various organs by the application of heat over the proper section of the spine, many times; and have permanently relieved menorrhagia in a number of cases, and checked metrorrhagia. Directly the hemorrhage ceases, and the womb contracts firmly, the bag should be removed, to be used again immediately if required. The bag should be refilled every hour and reapplied until satisfactory results are obtained, and taken away until again necessitated.

Small-pox	0	0
Varicella	8	0
Pertussis	2	4
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

Duration of Life.—A German statistician has obtained the following statistics in regard to duration of life: The average is thirty-seven years. Before the seventeenth year a fourth of the population dies. But one person in a thousand attains the age of one hundred years; six in a thousand reach the age of sixty-five years; 35,214,000 persons die during each year; 96,480 each day; 4,020 each hour; 67 every minute; while there are born 36,792,000 annually, 100,800 daily, 4,200 hourly, and 70 in each minute. The average duration of life is greater in the married than the unmarried individuals, among civilized than among uncivilized communities; while tall people are longer-lived than those of shorter stature. The chances for life, as regards men and women, are more favorable for the latter before the age of fifty, for the former after that age. Married persons bear the proportion to single ones as seventy-five to a thousand. Those born in the spring are more robust than those born at other seasons of the year. More deaths and births occur during the night than during the day.—*The Sanitarian.*

The Deportment of the Physician.—The *British Medical Journal*, commenting on the veto by the Governor of Georgia of the "Drunken Doctors Bill," says: "It is to be feared that the Georgia legislators do not stand alone in wishing to impose on the members of the medical profession a code of ethics different from that which is found sufficient for the rest of mankind. It is no doubt flattering that we should be thought to stand on a higher plane of morality than ordinary men, but at the same time this giddy ethical elevation has its inconveniences. A doctor is, after all, human, and it would be to the last degree unjust to condemn him to professional ruin for an offence which entails no such heavy penalty in the case of lawyers, engineers, men of business, and, we may venture to add, legislators. There might be something to say in favor of making drunkenness in itself a punishable offence wherever, or by whomsoever committed, but medical men may not unreasonably complain of being singled out from the community as fit objects for special temperance legislation."

A Smart Trick.—A Canadian medical student recently smuggled a skeleton into Canada from Detroit by dressing it up, properly padded, in woman's clothes, putting on it a hat and a thick blue veil, and seating it alongside of him in a buggy while crossing the ferry. After he had got it by the customs officers and into his own house, he learned that there was no duty on skeletons. His opinion of his own cleverness has fallen a degree or two.

Small-pox and Vaccination in Guatemala.—According to the *Gaceta Medica Quezalteca*, no fewer than twenty-five thousand deaths were caused by small-pox in one of the most recent epidemics in the Republic of Guatemala. Our contemporary is discreetly silent as to the havoc wrought by the disease in previous outbreaks, but the single item of statistical information just referred to *donne furieusement à penser*. Guatemala appears to be a veritable antivaccinationist's paradise: it has no vaccination laws of any kind, and the Government declines to concern itself about a matter which it probably looks upon as beneath the notice of legislators. We recommend Guatemala to the notice of the fanatics who wish to bring back free trade in small pox, as a climate more suited to their intellectual constitution than that of this country. England would, with perfect equanimity, see these new Pilgrim Fathers leave her shores for some less Jenner-ridden clime, where they could worship their favorite goddess Variola in peace, and where they would find the fullest scope for the exercise of their perverse statistical ingenuity.—*British Medical Journal.*

The Feeble-minded in Russia.—During the last five years, of 1,852,689 men between the ages of twenty and twenty-five who presented themselves for military duty in Russia, no less than 3,390 were discharged for mental unsoundness, or 1.8 to every thousand of the entire draft. In the Siberian districts 46,676 men were drafted, of which 117 were disqualified for the same reason, indicating 2.5 to the thousand. In the three Governments of Caucasia 3,327 men were called in and 20 of their number, or 6 to the thousand, were dismissed. Dr. Ignatieff, of St. Petersburg, taking those figures as a basis, estimates the number of feeble-minded in Russia proper as nine to every thousand of the entire population, and proportionally greater numbers in Siberia and the Caucasus.

Carbolic Acid as a Cosmetic.—There seems to be a belief in some of the rural districts of England that carbolic acid is good for the complexion, and with a desire of increasing as quickly as possible her beauty, a girl at Eastbourne took a large dose internally. The result was somewhat disastrous, though fortunately the would-be charmer's life was saved.

Medical Education in Portugal.—The medical curriculum in the University of Coimbra, Portugal, is of five years' duration. The first year is devoted to normal anatomy, histology, and general physiology; the second to topographical anatomy and operative surgery, special physiology and private hygiene, pathological anatomy and histology, and toxicology; the third to materia medica and pharmacology, surgical pathology, general pathology, and history of medicine, the fourth to internal pathology, obstetrics, and clinical surgery; and the fifth to clinical medicine, forensic medicine, and public hygiene. The University is provided with several laboratories and museums for practical teaching. Besides dissecting-rooms and an anatomical museum, there are histological work-rooms and a physiological laboratory; a work-room and museum of morbid anatomy and histology; an "arsenal" of operative surgery; laboratories of clinical medicine and toxicology, microbiology, materia medica, and pharmacy, and a "pharmaceutical dispensary." There are four clinics, two medical, one surgical, and one obstetrical (gynecology is nowhere mentioned, but perhaps it is included in the "tocological" department). Before entering the faculty of medicine students are obliged to go through a three years' course of preliminary study in the Mathematical and Philosophical Faculties. The first of these years is occupied with mathematics, inorganic and analytical chemistry; the second with organic and analytical chemistry and physics; and the third with botany, zoology, and advanced physics. The total course of study for the degree of Bachelor of Medicine is therefore of eight years' duration. For the higher degrees of Licentiate and Doctor further courses of special study are required, and they are only taken by "distinguished students."

SUGGESTIONS IN REGARD TO REFORMS OF THE PRESENT METHOD OF PERFORMING THE DUTIES OF CORONER IN THE STATE OF NEW YORK.[1]

BY STEPHEN SMITH, M.D.,

NEW YORK.

Sanitary Science.—Social order and public safety alike demand a complete revision of our methods of inquiry into deaths from unknown causes. At the very foundation of an intelligent and efficient administration of laws, rules, and regulations for the protection and promotion of the public health, are accurate vital and mortuary investigations and registration. No health authority can exercise its functions properly which does not thoroughly understand the causes of sickness and mortality among the people. Prevention is the sole duty of this branch of the public service, and no adequate remedial measures can be adopted and enforced for the protection and promotion of the public health without accurate information in relation to the causes of diseases, their sources, the laws which govern their development and extension, and the methods of control or prevention. This knowledge can only be adequately obtained by exhaustive inquiry into the circumstances and conditions under which every case of death occurs, by persons fully qualified to employ the latest resources of science in their investigations. We hold, therefore, that it is not only a legitimate function of the health authorities to fully investigate every death, but it is their duty in the interest of the public health and public safety. And especially is this obligation imperative in the cases of deaths from violence, or from sudden and unknown causes, for in general these deaths were preventable.

And such investigations by the properly constituted health authorities are equally essential to the proper administration of criminal justice. Medical science has now attained that perfection, in its methods and appliances in the investigation of the causes of death. that its conclusions have the certainty and exactness of the exact sciences. It has been repeatedly demonstrated that an expert medical examiner can trace in the tissues and organs of the dead the secret history of crime, and often fix the responsibility upon the criminal as no other form of evidence could. And in the same manner it has shielded from punishment the innocent, whom imperfect and superficial examinations of the dead would have condemned.

The reform proposed in this paper in the methods of investigating deaths from unknown causes, and the criminality involved in such causes, now lodged in the office of coroner, consists in a close alliance of the latter office with the local health boards of the State. It is evident that the duties of the coroner must be twofold, viz.: 1, a medical inquiry as to the cause of death, and 2, a judicial inquiry as to the perpetrator of the crime when death was effected by another party. These two inquiries differ widely in their scope and management. The first requires only expert medical knowledge, the second is purely judicial. Though both inquiries are important, the first takes precedence of the second, for on the accuracy of the former depends even the necessity of the latter. The preliminary investigation should properly, therefore, be made by the medical officer or officers of the board of health within whose jurisdiction the death occurred. The practicability of imposing this part of the investigation upon the health authorities is apparent when we consider how complete is the sanitary organization and service of the State at the present time. Every city, incorporated village, and town is now required by law to have a thoroughly well-organized board of health, as will appear from the following references to the Statutes:

Chapter 270, Laws 1885, provides as follows:

Section 11. "It shall be the duty of the Common Council, upon the nomination of the mayor of every city in this State, except in the cities of New York, Buffalo, Albany, Yonkers, and Brooklyn. . . . to appoint a board of health for such city, to consist of six persons who are not members of said council (one of whom, at least, shall be a competent physician). . . . The mayor of such city shall be a member, *ex-officio*, of such board of health, and shall be president thereof. The said board of health, when duly organized, shall appoint a competent physician (not a member of such board) who shall be health officer of such city."

Such is the provision for the organization of boards of health in the cities of the State, with the exceptions mentioned. The following is the plan of organizing boards for incorporated villages, provided in the same section:

"And it shall be the duties of the trustees of every incorporated village in this State to appoint, once in each year, a board of health of such village, to consist of not less than three nor more than seven persons (who are not village trustees). . . . The said board of health thus constituted shall elect a president and appoint a competent physician (not a member of such board) to be the health officer of such village."

Finally, the act provides for boards of health in townships, as follows:

"It shall be the duty of the supervisor, the justices of the peace, and the town clerk, in each town in this State, to meet in their respective towns within thirty days from the date of the town election of each year, and elect a citizen of such town, of full age, who with them shall constitute the board of health. The said board shall appoint some competent physician, not a member of the board, to be the health officer for such town."

Such is the law which gives to this State a completely organized public health service, whose jurisdiction covers its entire territory, and which takes cognizance of the health of every community, and of every birth, marriage, and death occurring in it. The powers of these boards are very large, as will be seen. Among the duties of the health officer is that of receiving, examining, and securing the registration of all certificates, records, and causes of death, and findings of coroners' juries. The board is empowered to designate the persons who shall grant burial permits for the burial of the dead, and transit permits for the transportation of the dead bodies of persons which are to be carried for burial beyond the limits of the county. And it is made the duty of undertaker, sexton, or other person having charge of the body of any dead person, to procure a record of the death, and its probable cause, duly certified by the physician in attendance on the deceased during his last illness; and there shall be no burial or removal of the body of any dead person until said duly certified record shall have been

[1] Read before the Section on Public Health of the Academy of Medicine.

presented to the board of health, or person designated by them, and until thereupon a permit for burial or transit shall have been obtained.

It is made a misdemeanor when any person neglects or refuses to make out or file for registration any record, or when any person causes, permits, or assists in the burial or removal of any dead body without a permit duly issued.

The board has power also to impose penalties, and to maintain actions in courts to collect penalties, not to exceed $100, for the violation of, or non-compliance with, its orders and regulations; to restrain by injunction such violations; to issue warrants to any constable or police, and to the sheriff, when necessary to bring to their aid the power of the county.

Finally, these local boards of health are under the jurisdiction of the State board of health, which is required to supervise their operations, and whenever they fail to perform their duties properly in the matter of registration of deaths, to take charge of the records and enforce the rules and regulations.

It is apparent from this review of the organization of the sanitary service of the State, that we have in operation a most complete system of verification of deaths, extending to the remotest districts and communities. In addition, the local boards of health embody in their membership all of the elements necessary to a thorough medico-legal investigation of every death having a suspicion of crime in its causation. The health officer is a competent physician, and experience proves that he is usually the most competent physician of the township. In the larger cities the staff of medical officers is composed of competent medical men, the selection being made from recent graduates from the schools and hospitals. Many of these boards also have chemical and pathological experts attached to the service, who may be called at any time to aid in the investigation of cases where their special knowledge would be useful.

But the question arises, if the boards of health perform all the duties required in the medical examination of suspicious deaths, what provision can be made to secure the proper discharge of the legal or judicial duties? As the coroner is recognized in the constitution of the State, the legislature can only regulate the office by assigning duties and prescribing the methods of their performance. The scheme herein proposed requires that there should be a court competent to make the preliminary inquiry into the criminal features of a case of death by violence, and though existing magistrates can lawfully act in that capacity, there is no doubt that the ends of justice would be more thoroughly subserved if there was in each county one or more persons, specially qualified, whose sole duty it should be to act as magistrates in these cases. These magistrates might be designated "coroners," and be elected as the constitution directs. The law should require, however, that the coroner should be a qualified attorney-at-law.

If the necessary legislation were secured to effect the reform here proposed, the result would be that in every city, village, and town throughout the State there would be competent medical examiners in the immediate vicinity of persons dying from causes having a suspicion of crime. Those examiners are now daily engaged in certifying to the causes of death of all persons dying within the jurisdiction of their respective boards of health, and are, therefore, the first to take cognizance of any death where there is a suspicion of crime. Every case which now requires a coroner's inquest would be at once made the subject of a preliminary examination by the health officers of the local board of health, and if there were any satisfactory evidences of crime all the necessary steps would be taken to have the inquest by the coroner complete in all of its details.

The practical operations of this new arrangement of the duties of coroners may be seen by applying it to a given county. The law provides that there shall be a board of health in every city, incorporated village, and town. In most of the counties there are four coroners, though in Onondaga County there is but one, while in Queens County there are seven, or one for each town. If we select Otsego County, we find that it has six incorporated villages, and twenty-four towns, which gives to its health duties thirty boards of health, and of course the same number of health officers. We could not by any scheme more effectually create a system of verification of deaths reaching to the most remote communities than is now organized and ready for immediate service. In the same county there are four coroners so located as to divide the territory properly among them. If they were lawyers, whose duties were limited to holding inquests without juries, and taking the necessary steps to secure the arrest and commitment of all persons implicated in the crime, the whole field of inquiry, medical and judicial, would be promptly and efficiently covered.

The following would be important features of a bill essential to secure the legislation necessary to carry into effect the proposed reform. To make the law operative in New York, Brooklyn, and perhaps some one or two other cities, which have peculiarly organized health organizations, special provisions should be made.

This outline of a bill embodies many of the provisions of the present law of Massachusetts, which has been in successful operation fourteen years. That law abolishes the office of coroner, and provides medical examiners in each county, appointed by the Governor. As we cannot abolish the office in this State by a legislative enactment, it seems wise to utilize the machinery which we have at hand as well as the office of coroner itself. Especially is this true when by such utilization a system can be perfected which gives promise of being even more effective than that of Massachusetts.

Section 1.[1] It shall be the duty of any citizen who may become aware of the death of a person who shall have died from criminal violence, or by a casualty, or suddenly when in apparent health, or when unattended by a physician, or in prison, or in any suspicious or unusual manner, to report such death forthwith to the health officer of the city, village, or town in which the body of the deceased person lies; or to any police officer, whose duty it shall be, without delay, to notify said health officer, or the president of the board of health, or commissioners of health of such death. Any person, except the health officer, who shall wilfully touch, remove, or disturb the body of any one who shall have died in the manner described in this section, or who shall wilfully touch, remove, or disturb the clothing or any article upon or near such body, without an order from the health officer, president of the board of health, or commissioner of health, shall, upon conviction, be adjudged guilty of a misdemeanor.

Section 2.[2] Whenever a health officer of any city, incorporated village, or town, appointed by the board of health thereof, as provided in Chapter 270, Laws 1885, has notice that there has been found, or is lying, within the jurisdiction of the board of health by which he is appointed, the dead body of a person who is supposed to have come to his death by violence, he shall forthwith repair to the place where such body lies and take charge of the same; and if on view thereof and personal inquiry into the cause and manner of the death, he deems a further examination necessary, he shall, upon being thereto authorized in writing by the president of the board of health of the city, incorporated village, or town where such body lies, in the presence of two or more discreet persons, whose attendance he may compel by subpœna if necessary, make an autopsy, and then and there reduce to writing every fact and circumstance tending to show the condition of the body, and cause and manner of death, together with the names and addresses of said witnesses, which record he shall subscribe. Before mak-

[1] This section consists of two sections of the present law.
[2] Modified Massachusetts Statute.

ing such autopsy, he shall call the attention of said witnesses to the position and appearance of the body.

Section 3.[1] If upon such view, personal inquiry, or autopsy, he shall be of opinion that the death was caused by violence, he shall at once notify one of the coroners of the city or county within which such body was found, and shall file a duly attested copy of the record of his autopsy in the office of said coroner. The coroner shall thereupon hold an inquest, which shall consist of the testimony of the health officer, and that of any other witnesses that the coroner may find necessary. Said inquest may be private, in which case any or all persons other than those required to be present by the provisions of this chapter, may be excluded from the place where the same is held, and said coroner may also direct the witnesses to be kept separate, so that they cannot converse with each other until they have been examined. The district attorney, or some person designated by him, may attend the inquest and may examine all witnesses. An inquest shall be held in all cases of death by accident upon any railroad, and the district attorney and the attorney-general may direct an inquest to be held in the case of any other casualty from which the death of any person results, if in his opinion such inquest is necessary or expedient.

Section 4.[2] The coroner shall have power to issue subpœnas for witnesses, returnable either forthwith or at such time and place as he shall appoint therein, and it shall be the duty of the coroner to give due notice of the time and place of the inquest to the health officer of the city, village, or town where the body was found, and it shall be the duty of said health officer to attend said inquest.

Section 5.[3] The coroner shall, after hearing the testimony, draw up and sign a report in which he shall find and certify when, where, and by what means the person deceased came to his death, his name, if known, and all material circumstances attending his death; and if it appears that his death resulted wholly or in part from the unlawful act of any person, he shall further state, if known to him, the name of such person, and if any person whose unlawful act contributed to such death, which report shall be returned by him to the next criminal court of record that shall be held in the county.

Section 6.[4] From and after the passage of this act no person shall be eligible to the office of coroner who is not a qualified lawyer.

Section 7.[5] Any justice of the peace, in each of the several towns and cities of the State, is hereby authorized and empowered, in case the attendance of a coroner cannot be procured within twelve hours after the discovery of a dead body, upon which an inquest is now by law required to be held, to hold an inquest thereon, in the same manner and with the like force and effect as coroners.

The Chinese Bone-setter.—A Western paper thus describes the method of treating a fracture employed by a Chinese doctor in that part of the country: "In setting a fractured limb he makes no effort to bring the bones into apposition, but simply takes a lot of red clay and envelops the limb with it. Then he takes some strips of bamboo and inserts them into the clay. Bandages are wrapped around those strips, and in the outer bandage he places the head of a live chicken. After he has secured this bandage he cuts the head off the fowl, allowing the blood to flow and penetrate the fracture. He then takes the chicken's head from beneath the bandage and covers the exterior with a thick coating of glue. The reason given for applying the chicken's head is that it nourishes the broken or fractured limb, and is 'heap good medicine.'"

ON ELONGATION OF THE LIGAMENTUM PATELLÆ AS A FACTOR IN THE PRODUCTION OF CERTAIN KNEE TROUBLES AND DIFFICULTIES OF LOCOMOTION.

By NEWTON M. SHAFFER, M.D.,

ATTENDING SURGEON IN CHARGE OF THE NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL; CONSULTING ORTHOPEDIC SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

In the year 1873 a man of about twenty-five years applied at the New York Orthopedic Dispensary, complaining of considerable difficulty of locomotion, and especially of great difficulty when going up and down stairs. The patient was supposed, by the physician who referred the patient to the dispensary, to have an insidious form of paralysis.

Various tests and a careful examination proved that there was no paralysis present. The patient then said his knees were very weak, and an examination of these joints showed a very peculiar state of affairs. The patellæ, when the patient was in a sitting position with the knees flexed just beyond 90°, were drawn above the condyles of the femur, and were lying in a plane almost horizontal with the long axis of the femur. The ligamentum patellæ on either side measured three and one half inches long, and the altered joint outline was characteristic of these peculiar conditions. The patient stated that he had to walk very carefully, or he would, upon the slightest lateral jar, dislocate one of his knee-caps outward, and fall suddenly to the ground. There was a slight knock-knee on either side, and there was present at the intercondyloid notch a very perceptible tumor—an apparent exostosis—which occupied the position at which the patellæ would normally rest.

Several attempts were made to relieve the condition by the use of apparatus. He finally obtained some comfort and a little relief by using a silk elastic knee-cap, with a lateral pad crescentic in shape and made of rubber, which prevented the outward dislocation of the patella. The patient was lost sight of. He knew no cause for his trouble.

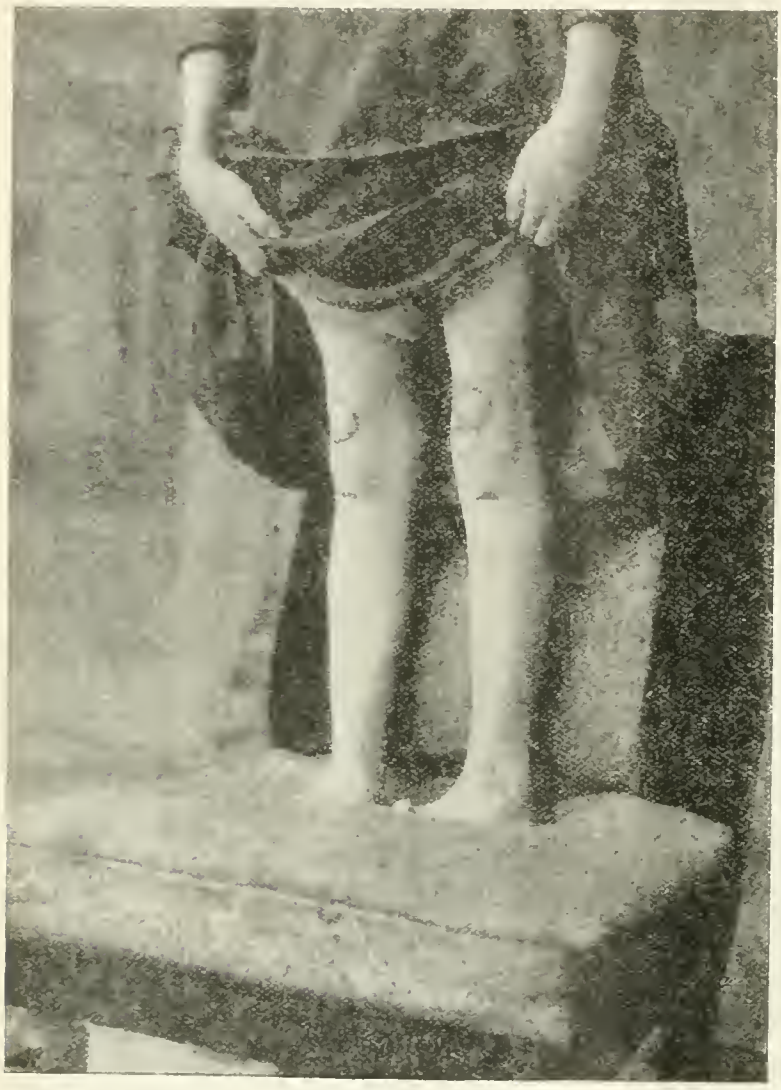
This case made an impression upon me, and a photograph was taken at the time, but it has become lost or mislaid in the years that have elapsed. It was not until a later period, when an opportunity occurred to watch the progress of a similar condition, that this case became of value.

In 1884 I was called by Dr. Janvrin to see a young lad, of fourteen years, who had hip-joint disease. The usual traction apparatus was applied, and, at the end of two years, the hip trouble was entirely removed. About this time, however, the patient began to grow very rapidly and to show signs of a progressive knock-knee. The member (right) affected with hip joint disease was quite straight, but the opposite side showed a very considerable genu valgum.

An examination of the ligamentum patellæ showed that it was three and one-quarter inches long on the left side, on the opposite side it was three inches long. The evident upward displacement of the patellæ on either side was marked during flexion of the knee at right angles. There was a distinct tumor in the intercondyloid notch on either side—more marked on the left; and the patient moved up and down stairs with an awkward gait, and fell at times without apparent cause. During his first summer in the country, after the hip disease was cured, he fell and dislocated his right patella. This was reduced by the family physician. The following year, he dislocated the left patella. In each instance the fall occurred while the patient was walking on an irregular surface.

The dislocation of the left patella proved a serious affair. The surgeon in attendance failed to reduce it, and, when the patient returned to the city, all attempts to reduce it seemed useless. When replaced, the bone immediately slipped back into its old position. At a

consultation, at which the late Dr. H. B. Sands, Dr. Janvrin, and myself were present, it was decided to make no further attempt at reduction, for the reason that the intercondyloid tumor and the elongated ligamentum patellæ would prevent the patella from moving in its true longitudinal plane. For the same reason, it was decided not to perform Macewen's operation, though the knock-knee was very considerable. Dr. Sands considered all these of sufficient importance to contra-indicate surgical interference.



With the use of my knock-knee apparatus the genu valgum was much reduced, and the patient now has a slight knock-knee—a dislocated patella on the left side, and a very serviceable knee on the right side. His left ligamentum patellæ is still three and one-fourth inches long; his right, three inches long. He can place his left knee in full extension, with the quadriceps extensor femoris acting upon the dislocated patella, which moves back and forth above, and to the outside of the outer condyle of the femur. When sitting with knee flexed, patient abducts and rotates thigh outward to secure the quadriceps action upon the patella. He flexes the knee by a semi-rotating movement. The tibia is rotated permanently outward, so that the tubercle of the tibia is fully one inch to the outside of its normal position. Even if the patella was in its normal position, its line of movement, taking the insertion of the ligamentum patellæ as a guide, would be directly through the outer condyle.

By careful treatment, and, especially, by avoiding traumatism, and by the use of a firm conventional leg-brace, which gives lateral support and prevents the outward rotating movement of the tibia upon the femur, the patient now walks from ten to fifteen miles a day.

I next saw a lady, Mrs. E——, aged about thirty-five years. She came to me, unable to walk except with great difficulty, and always with danger of falling. The least irregularity of the pavement would cause a fall. She had never dislocated her patellæ. There was slight knock-knee on either side. The ligamentum patellæ on either side measured three inches, and the patellæ occupied the position indicated in the accompanying photograph of Maggie M—— This patient had great difficulty in going up or down stairs, and the disability was almost identical with that produced by a transverse fracture of the patella with a long ligamentous union. Light lateral "leg braces," preventing lateral movement at the knee, and arresting the rotating movement of the tibia during flexion, gave this lady almost complete relief. She could walk with great comfort, and without any fear of falling.

The following history (condensed) is taken from the books of the New York Orthopedic Dispensary and Hospital:

Maggie M——, aged thirteen, admitted December 2, 1886. Two years ago fell on an orange peel; up to that time seemed all right. Since then, falls easily and frequently. When she first fell, dislocated left knee-cap, which was reduced by a woman who saw the child fall. Right patella dislocated about two months ago by a similar accident. After each fall, the knee swelled, and there was some pain, which gradually disappeared. Previous treatment "knee-cap," which did no good. Both limbs measure the same in length and circumference, being about normal. No knock-knee, very slight lateral mobility at knee-joint. Patellæ, when knees are at rest in full extension, lie above condyles and look obliquely upward and outward. Patellæ freely movable, and, when relieved of muscular action, they can easily be brought down to normal position. Disability in walking, etc., exactly like that produced by fracture of the patella with long ligamentous union. There is an evident exostosis at sulcus between condyles of femur. Length of left ligamentum patellæ two and three-quarter inches; right, two and five-eighths. The exact condition and relation of the parts is shown in the accompanying photographs, the tubercle of the tibia and the patella on either side being outlined by a dark line made before the photograph was taken.

The treatment consisted in the use of leg-braces limiting the lateral and rotating movements of the knee. The patient obtained some relief, but was lost sight of after a few months.

In the case of Miss X——, whose knees had been for a long time immobilized in plaster of Paris dressings, with a consequent fibrous anchylosis, the patellar ligament was stretched by the force required to break up the sub-patellar adhesions The right ligamentum patellæ is now two and three-quarter inches long; the left two and one-half inches long. An expressive disability exists in this case, occasioned partly by the reduced quadriceps power in knee use, and partly by a disagreeable "click," which occurs when the patella, especially on the right side, slides into its supra-condyloid position.

Several cases of elongated ligamentum patellæ have come under my observation since. I will briefly relate two:

A young man, Mr. W——, consulted me because he

had great difficulty in keeping up his part in playing lawn tennis. His knees, as he expressed it, "gave out very quickly." His patellar ligaments were nearly three inches long, and the disability was easily explained. He had considerable pain after prolonged use of his knees. Heat and swelling were sometimes present. He wore knee-caps without relief. He declined to submit to an operation which had for its object a shortening of the elongated ligament. He would not wear apparatus, and so long as he does not use his knees too much, he is now comparatively comfortable, though he has occasional attacks of pain and swelling after over-exertion.

A lady, Mrs. V——, well and strong, quite muscular, and, as she says, "never sick," found difficulty in going up and down stairs. In this case, the elongation of the patellar ligaments was very marked. The cause being explained, and the remedies proposed being rejected, nothing was done, though the patient's trouble seems to be increasing rather than otherwise.

I might relate other interesting cases where there was knee trouble due to the lengthened anterior patellar ligament. In some of them there was heat, pain, and swelling due to over-strain, but no true joint inflammation. In others a sense of weakness and debility. In others a tendency to dislocation of the patella outward. In all, however, there was a greater or lesser degree of disability under severe, or in some cases ordinary, use of the joint. It was especially noted where much strain was brought upon the articulation in the flexed position.

I have not succeeded in persuading any of my patients to have a section of the ligament removed. The operation seems both feasible and justifiable. Dr. Sands, in the case reported, declined, as before stated, to perform this operation, principally because of the apparent exostosis at the point where the patella glides between the condyles. This exostosis has existed in almost all my cases, and its cause is very obscure. It would seem to be a hypertrophy due to the lack of the normal pressure of the patella, which in its acquired position does not rest in the intercondyloid space.

I have measured many normal anterior ligaments of the knee since these cases came under my observation. Their normal length varies from about one-half inch in children to two inches in adult life. These measurements were made from the apex of the tubercle of the tibia to the lower edge of the patella, with the quadriceps in full contraction, with the knee bent at ninety degrees, thus making the ligament taut. In some adults the ligament is only a little over one inch long. In others, it is about one and one half, and in a few tall persons it is about two inches long, when measured as above. Anatomists vary very much as to the length of this structure. For example, Gray gives it as 3 inches; Ellis at 2 inches; Morris at $2\frac{1}{2}$ inches on its inner border, $3\frac{1}{2}$ on its outer border. But these measurements represent the ligament deprived of all contiguous tissue, and are made upon the cadaver. The ligament extends, for example, below the apex of the tubercle. Clinically, the measurements above are correct, both as applied to the normal and elongated patellar ligament, the points of measurement being the same in either case.

Shortening of the ligamentum patellæ is also a condition that I have seen quite often. It has always occurred as the result of a disused or paralyzed quadriceps extensor femoris muscle. In some cases, where the anterior thigh muscles are paralyzed. as in polio-myelitis anterior, the patella will rest against the tibia, and no trace of the ligament can be felt. The same may be said of certain cases of anchylosis of the knee, where the patella has been late in attaching itself to the subjacent bone. The ligament shortens under the influence of gravity, and a disused or paralyzed quadriceps, and it becomes very short after a time.

My experience proves that this condition, of an elongated ligamentum patellæ, is neither rare nor unique. As to its cause, I can find no satisfactory clew, except, of course, in cases like Miss X——'s, when force was used to dislodge the adherent patellæ. It is altogether likely that, in most cases, the condition is either congenital or acquired early in life; and the fact that the majority of my cases were women or children, the former being ladies of leisure and refinement, without the history of an injury, would seem to eliminate traumatism as a cause.

A peculiar feature of these interesting cases is the intercondylosed growth which, in Dr. Janvrin's case, gradually assumed the character of a considerable osseous tumor. As a mechanical factor, it prevents the normal movement of the patella over the trochlea, and it is a persistent barrier to a perfect restoration of the parts. In this case, three separate operative procedures were indicated to restore the parts to anything like a normal relation: 1, Macewen's supra-condyloid operation to remove the knock-knee; 2, to shorten the ligamentum patellæ; and 3, to remove the intercondyloid tumor. The result of the conservative treatment advised by Dr. Sands would seem to sustain his position that this complex operation was uncalled for.

My conclusions may be briefly stated:

1. Elongation of the ligamentum patellæ may produce weak, painful, and apparently inflamed knee-joints.

2. Many obscure knee-joint troubles, as well as impaired or difficult locomotion, may be explained by this condition.

3. Elongation of the ligamentum patellæ may produce a disability very like that produced by ligamentous union after transverse fracture of the patella.

And finally, elongation of the ligamentum patellæ may be, and very frequently is, produced by forcible breaking up a fibrous anchylosis of the knee-joint.

OPERATIVE TREATMENT OF DETACHMENT OF THE RETINA BY SCHÖLER'S METHOD; WITH A REPORT OF FIVE CASES.[1]

By CHARLES STEDMAN BULL, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO THE NEW YORK EYE INFIRMARY; CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL AND TO ST. MARY'S HOSPITAL FOR CHILDREN.

The views of Schöler[2] are based upon the modern theory of the causation or origin of detachment of the retina, which was first clearly and anatomically demonstrated by Leber and Nordenson in 1887. Heinrich Mueller in 1856 proved that the vitreous could only be detached from the retina, and the retina from the choroid, by shrinking or contraction in the connective-tissue portion of the vitreous. In 1867 Iwanoff demonstrated on pathological specimens that disease of the vitreous led to detachment of the vitreous, and that the latter preceded the detachment of the retina as an independent disease. In 1863, Von Graefe first called attention to the significance of perforation or laceration of the retina in its relation to detachment of the retina. In 1870, von Wecker stated that detachment of the retina was generally, if not always, preceded by both detachment of the vitreous and laceration of the retina. Finally, Nordenson in his elaborate work clearly demonstrated the process known as shrinking or contraction of the vitreous, followed this out to its natural conclusion, and proved that, as the process of detachment of the vitreous extended to the equatorial region, the retina, being here more intimately united with the vitreous, became torn, and through this rent the fluid which collected between the detached vitreous and the retina percolated, and thus gave rise to detachment of the retina itself. This view of the origin of detachment of the retina is now generally accepted.

It is not known who first suggested the injection of an irritating fluid into the sac of the detached retina, though Fano refers to it in his "Traité des Pratiques des Maladies des Yeux," p. 417, 1866. Galezowski tried it in 1871, but without any success.

In order that a detachment of the retina may be cured, Schöler lays down the following propositions:

1. It is necessary to produce such an adhesive retinitis as will antagonize the effects of a contracting or shrinking vitreous.

2. This irritative inflammation must be of moderate intensity, in order that the functions of the retina may not be injured.

3. If by this inflammation an absorption of the fluid between retina and choroid is promoted, it is desirable that the means (fluid) employed to develop it should be, to a certain extent, hygroscopic in character.

4. The means (fluid) employed should not injure the already diseased and degenerated vitreous, but should rather tend to act favorably also on the original choroidal disease.

5. The fluid employed must be antiseptic, and must be injected into the vitreous in front of the space between the latter and the retina, where it should tend to tear the shrinking or contracting bands in the vitreous, without causing any further detachment. In recent cases, by its hygroscopic properties it should act on the fluid between the retina and the choroid, through the laceration of the retina itself.

In the course of his investigations, Schöler made experiments on animals with tincture of iodine, biniodide of mercury, Lugol's solution, sublimate solutions, and glycerole of iodine solutions. Some of these were too weak, causing changes in the retina indeed, but which were transient and inconstant. Some of them were too strong, like the glycerole of iodine. The tincture of iodine gave constant results. After an injection of six drops of the latter, changes appeared during the next six or eight days, such as chorio-retinitis with diffuse cloudiness of the pre-retinal layer of the vitreous, which subsequently subsided. Schöler first used the tincture of iodine in the human eye, on November 22, 1888, in a woman in whose eye the detachment occupied about two-thirds of the retina. In eight days there was a marked improvement, and the patient was able to read. In fourteen days there was a relapse, with two concentric annular detachments. A second injection was made into the vitreous, which was followed by pain, conjunctival congestion, retinitis, and cloudiness of the vitreous. A recession of the chorio retinitis took place slowly, but eventually the retina became reattached.

Schöler states that the tincture of iodine injected into a space filled with serum and albumin, is diluted and extends for some distance over the retina and between it and the vitreous. The possible bad effects of the injection of tincture of iodine into the vitreous depend: 1, On the toxic properties of the drug; 2, on the possible formation of thrombi in the veins; and 3, on the direct extension of the drug through the lymph-spaces of the eye into the cerebro-spinal fluid. The first danger, Schöler considers, is met by the well-known fact that large quantities of the drug are frequently injected into the thyroid gland in goitre, without producing any bad results. The danger of the formation of thrombi is offset by the fact that in aneurisms the aim is to form a thrombus by the injection. The danger of the entrance of the drug into the cerebro spinal fluid is probably offset by the fact that in spina bifida large quantities of the drug are frequently injected into the spinal canal without dangerous results.

The views of the profession as to the value of Schöler's method vary greatly. Schweigger is opposed to it except in cases from which nothing more can ever be expected.[1] Becker quotes Kühne's statement that in frogs the retinal function returns as soon as the cone is again in contact with the pigmentary layer, and suggests that the same should occur in recent detachments in man if we can bring the cones in place. In old detachments, the rods and cones are destroyed, and of course there is then no hope of restoration of vision by any means. Abadie believes in the efficacy of the method and thinks it should be tried.[2] He reports nine cases, with success in some of them. He never injects more than three drops of the tincture of iodine. If the dose is too large the reaction is very great, and is followed by rapid disorganization of the media of the eye. He has a knife made for the purpose, shaped like a Graefe cataract knife but with a stronger blade, and with the back hollowed into a shallow gutter, and the shank and handle are a Pravaz syringe. The injection is thus made without withdrawing the knife. The amount to be injected is regulated by the extent of the detachment. If the detachment is extensive, he makes two injections on opposite sides of the eye, and the second injection, he claims, almost always brings success.

Panas reports good results, but is in doubt whether they are due to the injection or to the simple puncture.[3]

[2] Archives d'Ophthalmie, p. 461, 1889.

[3] Idem, p. 257, 1890.

Gelpke reports a case which terminated fatally. The patient was a man, aged sixty-six, who had a detachment of unknown origin, and involving about three-fourths of the retina. He had perception of light and the tension was — 3. The antiseptic precautions taken at the operation were painfully minute. Three drops of tincture of iodine were injected into the vitreous, which set up infectious purulent choroiditis, which in its turn induced acute meningitis, ending in death on the sixth day.[1]

For the performance of his operation Schöler had a special instrument constructed, which he describes as follows: Upon the end of a Pravaz syringe is fastened a gold-plated platinum tube, shaped like a strabismus hook, which ends in a small knife, curved like a hook. The length of the gold-plated platinum tube is 4 ctm., and its thickness 2 mm. The length of the little knife is 2¼ mm., and its width 1¼ mm. At the junction of the knife with the tube there are two small openings, 0.3 to 0.5 mm. in diameter, which are prolonged on each side of the blade into a short, shallow gutter, to conduct the fluid from the syringe into the eye.

All Schöler's experiments on animals and man tend to prove that there are substances of differing medical properties, which may be injected into the vitreous with safety for the purpose of bringing about a cure of detachment of the retina. As a rule, the earlier the fluid is injected after the detachment is recognized, the better; for the less contraction has taken place in the vitreous, the better is the prognosis. The most favorable place for the injection to be made is the point at which the retinal detachment began, in order to establish as near as possible to the point of traction of the contracting vitreous bands the mechanical antagonizing factor set up in the retina by the irritative inflammatory process and its consequences.

Schöler considers that the two most favorable factors for the success of the operation are: 1, A slight sagging of the detached retina, showing the presence of a small amount of fluid; and 2, the recent occurrence of the detachment. On the contrary, the unfavorable factors are: 1, Simultaneous disease of the vitreous with flocculent opacity and fluidity; 2, the existence of excessive myopia; 3, a wide extension of the detached part of the retina; 4, co-existence of more or less advanced disease of the choroid.

After the operation a bandage is applied, merely for the purpose of aiding in closure of the external wound. The patient should remain on his back in bed for at least a week, and sometimes for two weeks.

Schöler draws the following conclusions:

1. He considers that his experiments give the first demonstration of the fact that different medicated fluids may be injected free into the vitreous, in front of the retina, without necessarily endangering the eye, and may induce the development of a healing process.

2. The injection of tincture of iodine into the vitreous through the retina may induce the rupture of abnormal adhesions between the vitreous and the retina, and may set up a plastic retinitis, which, together with the hygroscopic absorbent and disinfecting properties of the iodine, may bring about a cure of the detachment.

3. The process of development of the cure, and the clinical progress of the case, with a slowly increasing visual acuity, widening of the visual field, and diminution of the night blindness, justify the assumption that these curative processes are lasting. Of course the ultimate prognosis must be based upon the lapse of time, that is, the duration of the improvement.

Case I.—Thomas B——, aged twenty-eight; first seen September 23, 1889. In March, 1888, he had received a violent blow on the right eye, which caused total blindness for a few minutes, and great pain. The vision then slowly returned, and in the course of about ten days all signs of visual disturbance had disappeared. Three months before I saw him, while ill in bed, he read for hours at a time while lying on his back by insufficient light. After some weeks he began to have symptoms of asthenopia, and awoke one morning with a defect of vision in the right eye which annoyed and startled him, because he could not see the upper portions of any object. An examination revealed the following condition:

Right eye: V.=$\frac{15}{200}$ eccentrically and unimproved; cornea aqueous and lens clear; vitreous fluid and containing numerous floating opacities, but no distinct membrane; iris fluttering; detachment of the retina downward and inward, and apparently recent. Left eye normal in every respect.

The patient was immediately placed on his back in bed, and was not allowed to rise except to answer the calls of nature. The eye was kept under the influence of atropia, and pilocarpine was administered hypodermically. He did not bear the pilocarpine well, though its physiological effects manifested themselves promptly, and it was discontinued on the fourth day. In its place small doses of potassium iodide, largely diluted, were administered. This treatment was continued for four weeks, and an ophthalmoscopic examination was made nearly every day. During this period the vitreous became clearer and the floating opacities diminished, but there was no visible change in the detachment of the retina, and none in the visual field. Schöler's operation was then suggested to him, and he was informed of the possible dangers of the step, as well as of the advantages claimed for it, and he decided to have it done. Five weeks from the date of his first visit the injection was made, the instrument used being similar to that devised by Schöler. The eye was anæsthetized by cocaine, having previously been rendered thoroughly aseptic, and the puncture was made between the inferior and internal recti, and well in front of the equatorial region. The operation was done under ophthalmoscopic examination and without fixation of the eyeball, and as soon as the point of the knife-needle was seen in the vitreous three drops of tincture of iodine were injected very slowly. The vitreous became cloudy very rapidly and the intraocular tension rose at once. A bandage was then applied, and the patient at once put to bed. In the course of a few minutes the patient complained of a boring pain, which during the next hour increased in severity, but was never unbearable, and disappeared during the night. The bandage was removed the next morning, and slight conjunctival injection was found. The wound through the conjunctiva had already healed. The vitreous was still cloudy with several reddish brown flocculent opacities floating about. Whether these were fresh blood-clots, the result of the operation, or merely flocculi colored by the iodine, could not be settled. The condition of the detachment could not be determined. On the second day the vitreous was much clearer, and the detachment could be made out, apparently smaller and withdrawn toward the periphery. No pain and no signs of any serious intra-ocular inflammation. On the third day the vitreous was still clearer, and a distinct yellowish-white band could be made out, running from a point at the extreme periphery of the infero-nasal quadrant toward the centre of the vitreous. Only one brownish red floating opacity could be discovered. The patient was kept in bed for another day as a precautionary measure. On the fourth day the patient was allowed to rise, and a test of the vision and of the visual field was made. Vision was reduced to $\frac{10}{200}$ and the visual field was practically unchanged, perhaps a trifle widened. The signs of chorio-retinitis subsided, and as there had been no material improvement in the field, and as the vision was slightly worse than before the operation, the patient was discharged with directions to report in a week.

In this case the signs of inflammatory reaction were surprisingly slight and very transient in duration. The patient did not report until nearly two weeks had elapsed; but he had not attempted to use his eyes for any purpose, and the operated eye had given him no trouble, and

[1] Centralbl. für Prakt., p. 260, August, 1889.

he claimed that the vision had improved. An examination showed a decided change in the fundus. The vitreous was very much clearer and there were no floating opacities. The yellowish-white band of tissue running from the point of puncture toward the centre was much smaller and more condensed, and more sharply outlined. The detachment was decidedly less in extent, and there was a quite extensive patch of plastic chorio-retinitis at the extreme periphery of the fundus, around the region originally occupied by the detachment. Vision had risen to $\frac{15}{200}$, and there was a slight widening of the visual field.

The reaction following the first injection had been so slight, and the vision had so soon returned to the degree existing at the time of the operation, that I suggested to the patient that he have a second injection made, but this he declined, and I was not enthusiastic enough in the matter to urge it. The point that impressed me most in the progress of this case was the exceedingly slight reaction following the injection. The existence of the band of fibrous tissue running from the point of puncture into the vitreous must be regarded as of grave significance. As the contracting process goes on in the eye, the presence of this band of tissue will tend inevitably to detach the vitreous from the retina, or the latter from the choroid, at a point opposite to the site of the original detachment, and the case may thus end in total detachment of the retina. It seems, therefore, a fair statement to say that the condition of the eye of this patient has not only not been improved by the operation, but has in all probability been made worse. This is, of course, making a forecast of the future, and thus far no such unfortunate change has occurred. The patient has been repeatedly examined at intervals of a few months, and the vision and field of vision have remained practically unchanged.

Case II.—Miss Margaret M——, aged thirty-one; first seen April 24, 1890. Had always had very strong eyes, and had used them constantly for all kinds of fine embroidery. Never noticed anything to complain of until about two months before I saw her, when she observed a steadily increasing cloudiness of the vision of the right eye. This grew worse, until now she can only see the lower parts of objects with the right eye. An examination revealed the following condition of affairs: Right eye: $\frac{15}{200}$, unimproved; cornea aqueous and lens clear; hyalitis with delicate cobweb-membrane running across the vitreous and attached to the optic disk; numerous floating opacities; retina detached downward and outward. Left eye: $\frac{18}{15}$, Hm. + D. 1; media and fundus normal.

Owing to the presence of this delicate cobweb-membrane, I decided to divide it before taking any steps to treat the detachment of the retina, and this was done in the way before described in two articles previously published on the subject, with the narrow, double-edged needle. The eye was then bandaged and the patient put to bed, atropine having been previously instilled. The next morning the bandage was removed, and the cobweb-membrane had retracted in both directions. The patient was kept in bed for three weeks, and an injection of pilocarpine hydrochlorate was given hypodermically every other day. She bore the drug very well, and the diaphoresis was complete, but at the end of the third week her health, never very good, began to fail, and the treatment was discontinued and the patient allowed to rise. No change had taken place in the vision for near objects, though distant vision had risen to $\frac{18}{10}$ +, but the defect in the visual field remained the same. She then decided to have Schöler's operation done, though I did not urge it. Eight days later the right eye was cocainized, and under the strictest antiseptic precautions and by ophthalmoscopic examination, a puncture was made in the infero-temporal quadrant, between the inferior and external recti muscles, the point of the needle being carried well into the centre of the vitreous, and four drops of tincture of iodine slowly injected. Sharp pain was complained of at once, and a solution of cocaine and atropine was dropped in. Before the bandage was applied an ophthalmoscopic examination showed a general brownish haze through the vitreous. The pain subsided after a few hours, in spite of the increased tension, and the patient passed a good night. The next morning there was considerable conjunctival injection and the tension was still above normal. The vitreous was so cloudy that only a very faint red reflex could be obtained with the ophthalmoscope. The atropia was discontinued and cocaine used in its place, and the bandage was left off permanently. On the second day there was a well marked ciliary injection, some chemosis of the conjunctiva, and an invisible fundus. Hot applications were applied constantly, and as the patient complained of continuous pain, two leeches to the temple. On the third day the symptoms of intra-ocular inflammation were decidedly less marked and the pain had almost disappeared, but it was not until the fifth or sixth day that the infiltration of the vitreous began to clear up. From this time on the symptoms rapidly subsided, and on the twelfth day all ciliary and conjunctival injection had disappeared, the chemosis was gone, there was no pain, and a tolerably clear vitreous. There was no trace of the previous cobweb, but there was a broad dense band of tissue running across the vitreous, from a point downward and outward, the site of the two punctures, in a direction upward and inward, and decidedly backward, partially concealing the optic disk from view. With a widely dilated pupil, only a small detachment of the retina could be discerned at the extreme periphery. A test of the vision showed a decided diminution to $\frac{3}{200}$ eccentrically. Examination of the field of vision showed a decided improvement peripherically, but there was an irregular broad defect extending nearly across the centre of the field.

The condition of this patient had therefore been made decidedly worse by the operation, and at one time there was a fear that a destructive panophthalmitis had been set up.

One week later the vitreous was very much clearer, and the fibrous band across the vitreous seemed narrower. A somewhat extensive exudative or plastic chorio-retinitis was seen downward and outward, and the detachment of the retina had changed its position and its shape, and was now more directly downward. It, however, was apparently of about the same extent as before, and the defect in the visual field was relatively of the same size.

Case III.—Mr. W. A——, aged sixty, first seen May 11, 1890. Has been myopic all his life and has worn glasses for thirty-five years. Has persistently abused his eyes for many years. In March, 1890, he suddenly noticed a small black spot downward and inward in front of the right eye, which has steadily increased in size, until now it covers nearly half of the field of vision. Vision is now eccentric with this eye, and there is a constant dull pain in the eye, and great photophobia. An examination showed the following:

Right eye: V. = $\frac{18}{100}$ eccentrically and unimproved; cornea and aqueous clear; iris fluttering; peripheral opacities in both lenses; floating opacities in vitreous; patches of diffuse chorio retinal degeneration; detachment of nearly the entire upper half of the retina, and the remaining portion blunted as to the perception of form and color.

Left eye: V. = $\frac{18}{100}$ − : with sph. − D. 2 ⌒ cyl. − D. 2.50 ax. 180° = $\frac{18}{30}$ +; floating opacities in the vitreous, and patches of diffuse chorio retinal degeneration; field for form unrestricted; no detachment.

This patient was a severe sufferer from chronic rheumatism, and could not be subjected to the long confinement in bed. He was, therefore, put on a tonic treatment together with small daily doses of pilocarpine hypodermically. The physiological properties of the drug appeared very promptly and he bore it very well, but at the end of the second week he began to lose his appetite and became very restless, and it was stopped. An examination then made showed a slight improvement of the vision in the

right eye, with a sph. — D. 2 to $\frac{1}{40}$ + ; but there was no change in the defect of the visual field, and none apparently in the detachment of the retina. He was then told that all had been done for him except an operation, which was described to him in detail. He was told that his case was a bad one, that the left eye was in an unsatisfactory condition, and that the operation might not only destroy what sight he had in the right eye, but might also endanger the left eye. On the other hand, he was told that the retina in the right eye would almost certainly become entirely detached in time, and that the operation might prevent this. After deliberation he decided to have the operation performed. This was done while in the sitting posture, with the usual antiseptic precautions, and under ophthalmoscopic examination. The puncture was made in the supero-temporal quadrant of the eyeball, just back of the ciliary region, between the superior and external recti muscles, and three drops of tincture of iodine were slowly injected. The vitreous became of a brownish color at once, and before the bandage was applied was so cloudy that the fundus could not be seen. Little or no pain followed, but the tension increased. There was some pain during the night and the next morning, but nothing of a severe character. When the bandage was removed chemosis of the conjunctiva had already taken place, and a deep injection was rapidly developing. The pain became intense, the lids became swollen, and before the end of the day panophthalmitis was in full blast. This was combated by atropine, leeches to the temple, and hot bichloride fomentations, but the inflammatory process lasted more than a week before the symptoms began to subside. The disease ran the usual course and at the end of the fourth week the eye was in a quiescent condition, and could be carefully examined. The iris was decidedly atrophic and adherent to the lens-capsule. The opacities of the lens had increased and encroached on the field of the pupil. The vitreous was filled with bands of exudation, that were so dense that no view of any details of the fundus could be made out. The tension was decidedly below normal, and vision was reduced to recognizing the movements of the hand eccentrically. Fortunately the severe inflammation through which the right eye had passed, had not as yet caused any positive defect in the left eye. There was no sympathetic irritation developed, and no ophthalmoscopic complication appeared in the left eye. But in the operated eye the vision had sunk from $\frac{18}{100}$ to distinguishing the movements of the hand eccentrically. The vitreous was filled with bands of fibrous tissue, which concealed all view of the fundus, and the natural inference is, that so far from the detachment of the retina having been diminished, it was probably increased by the results of the operation. It is certain that the condition of the patient was made decidedly worse by the operation.

Case IV.—Mr. M. H——, aged seventy-three, first seen September 30, 1890. Patient has always been myopic and has worn glasses for many years, but has never consciously abused his eyes and does not wear glasses in reading. He began to notice a failure of the vision of both eyes about a year ago, and about eight months ago it grew suddenly very much worse in the left eye. This was recognized at the time as due to a detachment of the retina, for which he went through the usual rest-cure, but without any benefit. When I examined him the conditions were as follows :

Right eye : V. = $\frac{18}{200}$, and with sph. — D. 3 = $\frac{18}{40}$; reads Jaeger No. 3 with sph. + D. 2 ; peripheral opacities in the lens and floating opacities in the vitreous ; usual atrophic myopic fundus.

Left eye : V. = perception of light ; peripheral opacities in the lens ; detachment of the retina downward, inward, and outward.

In view of the patient's advanced age, the degree of myopia present, and the fact that the patient had been subjected to the rest-treatment on his back in bed for a period of nearly six weeks, together with the use of atropia and the internal administration of potassium iodide, without any benefit whatever, the case was regarded as a desperate one. Schöler's operation was proposed to him, together with its accompanying dangers, and he decided to have the attempt made. On October 2d the left eye was cocainized, and the puncture was made in the infero-temporal quadrant, just back of the ciliary region, and between the inferior and external recti muscles. Four drops of tincture of iodine were slowly thrown into the vitreous, which almost immediately caused a brownish turbidity and rendered everything in the fundus invisible with the ophthalmoscope. Quite a sharp pain was almost immediately complained of, which radiated from the eye back upon the temple and over the forehead. This increased until it soon became so violent that it was necessary to administer a hypodermic injection of morphine. The sharp pain soon passed away, leaving behind it a dull ache both in the eye and head. The next morning the bandage was removed and the eye examined. There was a very marked and general chemosis of the ocular conjunctiva, but not much injection. The tension was increased to + 2, and the fundus was entirely invisible. The objective signs of intra-ocular inflammation were more marked than is usual in an ordinary acute chorio-retinitis, but the application of leeches, atropia, and hot fomentations caused a gradual subsidence of the inflammation, and on the eleventh day I was enabled to obtain a view of the fundus. There was no change in the appearance of the lens, but the detachment of the retina had receded over more than half its extent, and seemed to be confined to the infero-nasal quadrant. There were some brownish flocculi floating in the vitreous, but no bands of new tissue were visible. Vision had improved to counting fingers at a distance of eight inches, and the field had widened. This patient, in spite of his years, made an excellent recovery, and was enabled four months later to read $\frac{10}{200}$ with the left eye. A portion of the retina in the infero nasal quadrant still remained detached, but downward and outward it had become reattached, and the signs of a plastic chorio retinitis were extremely well marked. The widening of the field which was noticed on the eleventh day still remained, and had even gained somewhat in extent. Unfortunately this improved condition of the fundus did not last. About the middle of December the vision became again more obscured, and an ophthalmoscopic examination showed that the detachment had again taken place, and was as extensive as at first. The chorio-retinitis had extended, and the degeneration had evidently advanced in part to the atrophic stage. The opacities of the lens had increased and extended well into the nucleus, and vision was reduced to recognizing the movements of the hand. The lens has since become entirely opaque, and the patient has the merest quantitative perception of light.

Case V.—Mr. B. W——, aged thirty six, first seen December 28, 1890. Has always had good eyes and has used them steadily day and night. Several months ago he began to have foggy vision in the right eye, and a dull ache after long-continued reading. He has had a refractive error which turns out to be compound hypermetropic astigmatism. Soon after this he began to complain of the left eye also. Was examined by an oculist who told him that he had disease of the retina of both eyes, and that he must stop all work. When I examined his eyes I found the following condition :

Right eye ; $\frac{18}{100}$ + : with sph. + D. 1.75 ⌒ cyl. + D. 1 ax. 75° = $\frac{18}{50}$; cornea, aqueous, and lens clear ; organized membrane in the vitreous ; patches of old chorio-retinitis, and one or two of fresh exudation ; detachment of retina inward of moderate extent ; reads Jaeger No. 2 slowly with above sphero cyl. glass.

Left eye ; $\frac{18}{200}$: with cyl. + D. 2.50 ax. 105° ⌒ sph. + D. 1 = $\frac{18}{50}$; reads Jaeger No. 3 with same combination ; cornea, aqueous, and lens clear ; quite extensive patches of chorio-retinitis, but no demonstrable detachment.

This patient was very anxious about his condition, and was willing to submit to any treatment that offered a chance of success. He was put on his back in a darkened room, with atropia in his eyes, and a bandage over the right eye for six hours daily. In addition pilocarpine was administered hypodermically daily for eight days. The physiological effects of the drug manifested themselves promptly, but without any bad result until the eighth day, when he had an attack of heart failure which nearly carried him off, and from which he did not entirely rally for nearly twenty-four hours. The administration of the drug was of course permanently stopped, but the rest of the treatment was persisted in for nearly two months. Not the slightest benefit resulted from these weary weeks in bed, and, after he had somewhat recuperated, Schöler's operation was suggested to him and immediately accepted. His vision in the right eye was still $\frac{18}{50}$ with the compound cylinder, but he could no longer read Jaeger No. 2. On February 26th I punctured the eyeball on the nasal side, just below the inferior margin of the internal rectus muscle, and just back of the ciliary region, and injected slowly into the vitreous four drops of tincture of iodine. The vitreous became immediately very cloudy, and the tension rose to + 2, and he complained of some pain, not severe but very persistent in character, and located entirely in the eyeball. The next morning the bandage was removed and considerable conjunctival and ciliary injection was found. The tension was somewhat less than the day before, but the fundus was still invisible. There was no chemosis and no sign of any severe intraocular inflammation. The vitreous remained persistently cloudy for nearly three weeks. At the end of that time an ophthalmoscopic examination showed some flocculi in the vitreous, an increase in the density of the membrane which previously extended across the vitreous, and a decided increase in the detachment. His vision had sunk to $\frac{1}{200}$, and the field of vision was perceptibly narrower than before the operation. This patient was kept under observation for several months, and a gradual change was observed in the fundus. The nasal portion of the retina became slowly reattached, as if due directly to a contracting process going on in the plastic chorio-retinitis set up at the point of injection; but it seemed as if the detachment simply shifted its location from the inner to the inferior quadrant of the retina, as the defect in the visual field was upward. The membrane in the vitreous grew somewhat thinner, and the floating flocculi entirely disappeared. The most unfavorable symptom was a decided increase in the number and extent of the patches of chorio-retinitis, without doubt set up by the operation. At the last examination made the patient's vision was $\frac{15}{200}$, unimproved by any glasses, and the defect of the visual field occupied fully a quarter of its extent, and directly upward. This patient has not been seen since the latter part of February, but in a letter received from him in April, and dictated, he stated that his vision had decidedly failed, as he could only recognize the large letters of the test-types when held close to his eye, and then only in the lower part of the field of vision.

A brief *résumé* of the histories of these five cases may assist in drawing some conclusions.

The first case was a young man, with previous history of injury to one eye, in whom the detachment occupied about one-third of the fundus. The injection caused very little reaction, but the primary effect was a diminution of the existing visual acuity. Subsequently the vision improved and the field widened. Plastic chorio-retinitis causing adhesion of the retina to choroid was undoubtedly the cause of this, but the formation of additional fibrous bands in the vitreous will probably lead to a further increase of the detachment, and probably to permanent loss of vision.

The second case was a young woman, with hypermetropia and a perfectly normal fundus in one eye, but with a cobweb-membrane and a detachment of the retina in the other, occupying about one-third of the fundus. The injection caused a somewhat more violent reaction than in the first case, but soon subsided under active treatment. The effect of the operation was to make the vision decidedly worse, and caused no diminution of the detachment, but simply shifted it from one quadrant of the eye to another quadrant. Rather extensive plastic chorio-retinitis, and the formation of fibrous bands in the vitreous were decidedly bad results.

The third case was a gentleman, aged sixty, who had compound myopic astigmatism and a diseased choroid in both eyes, with detachment of the retina in one eye. The injection caused acute infectious panophthalmitis, which ended in nearly total destruction of vision in this eye, and an apparent increase in the extent of the detachment, though this could not with certainty be made out.

The fourth case was a gentleman, aged seventy-three, who had myopia and diffuse choroidal disease in both eyes, and a very extensive detachment in one eye. The injection caused an acute panophthalmitis of moderately severe type, which yielded to treatment in about two weeks. The primary effect was an improvement in the vision and a decided lessening in the extent of the detachment, more than half of the detached portion becoming reattached. But the ultimate effect was a recurrence of the detachment and a reduction of the vision to what it was before the operation was done, and subsequently an opacity of the lens.

The fifth case was a gentleman, aged thirty-six, with compound hypermetropic astigmatism and a diseased fundus in both eyes, and a small detachment of the retina in one eye. The injection caused only moderate reaction. The primary effect was an increase in the detachment and a further loss of vision, but subsequently the retina became reattached at the inner quadrant and detached below, and vision rose to $\frac{15}{200}$. Two months later his vision had again sunk to $\frac{6}{200}$, and the detachment of the retina had become more extensive.

THE BLOOD-CHANGES IN THE MALARIAL FEVERS.

By ARTHUR C. BRUSH, M.D.,

BROOKLYN, N. Y.

The presence of a specific organism in the blood of patients suffering from the malarial fevers has been clearly demonstrated by the researches of Laveran, Osler, Carter, Moore, and Prout; but the descriptions of these organisms as given by these writers have varied, and this variation, when viewed with the different clinical types which these fevers present, is suggestive that there is a connection between them, and that it is to this difference in the species of organism that the difference in type is due, and that the change in type which these fevers often present may be due to the subsequent development of a new species, and that under the name malarial we are really including several distinct but closely allied conditions. The different species of organisms, as a rule, occur together in the same case of the malarial fevers seen in this city, but cases occur in which one type alone exists or greatly predominates over the others.

I have been unable as yet to differentiate my cases clinically, for most of my histories are very imperfect, most of the cases having been seen only once or twice. The specimens were all obtained from cases in my clinic in the City Dispensary. The blood was obtained in the usual way from the finger, and either studied fresh or mounted in a saline solution, usually both methods being employed together.

I have been able to separate my cases into three groups: *a*, Those in which the non-pigmented intercorpuscular bodies alone existed; *b*, those containing the pigmented intercorpuscular bodies, flagellæ and crescents; and *c*, those in which both kinds existed together. This division is in accordance with the teachings of Osler, who in writing of the non-pigmented intercorpus-

cular bodies, says: "They are not an earlier stage of the pigmented bodies, but a distinct species;" and Prout found only this species in his cases. In my cases the first set was the least common, and I found but two.

Case I.—J. G—— (August 20, 1891). Has had attacks of "malaria" for the past two years. Present attack commenced the day before yesterday, when she had a rigor followed by fever and sweating. Begins to feel unwell now. Spleen enlarged. Examination shows the red corpuscles to contain one or more oval hyaline bodies, with a few rod-shaped ones.

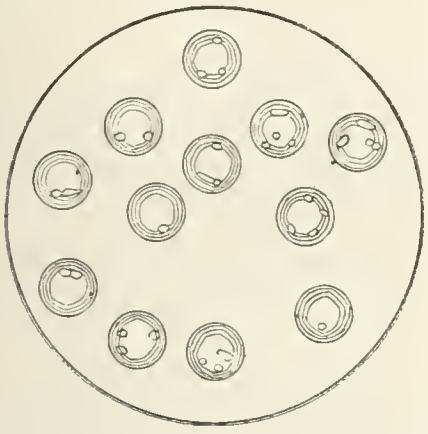

Fig. 1.

August 27th.—Patient has had a continued fever since last night, with a slight chill every day. There is some pain in the head, back, and limbs. Examination shows the oval bodies to be almost entirely replaced by rod-shaped ones, and vacuoles have developed in some of the cells. Large masses of protoplasm have appeared, containing large and small pigment grains.

Case II.—F. M—— (August 6, 1891). She has had malarial fever every fall for many years. Present attack

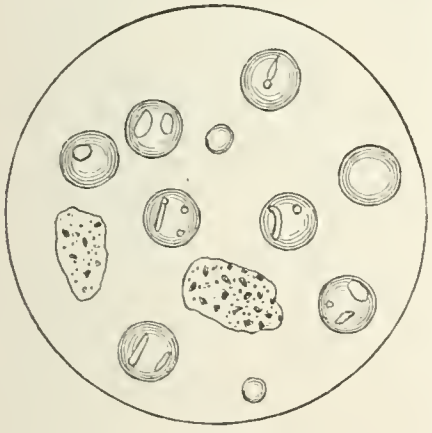

Fig. 2.

commenced six weeks ago. Since then she has had a continued fever, with irregular rigors. Patient is very anæmic and sallow. Spleen much enlarged; temperature, 101½° F. Neuralgic pains in the head and pains in the bones. The red corpuscles contain oval and rod-shaped hyaline bodies and vacuoles. The white blood-cells are increased to one in fifty, and are loaded with variously sized pigment grains. Very large and very small and nucleolated red corpuscles are also present.

It will be seen that both these cases are of the type of a continued fever, and that some of the blood-changes in the second point to an etiological relationship to leucocythæmia. Of the second set of cases, or those containing only the pigmented intercorpuscular bodies and the free forms found associated with them, I have found six cases; four of these were of the quotidian intermittent type and two of the remittent type.

Case I.—C. T—— (October 10, 1891). Has had intermittent fever every fall for the past seven years. Present attack commenced yesterday, when he had a chill, fol-

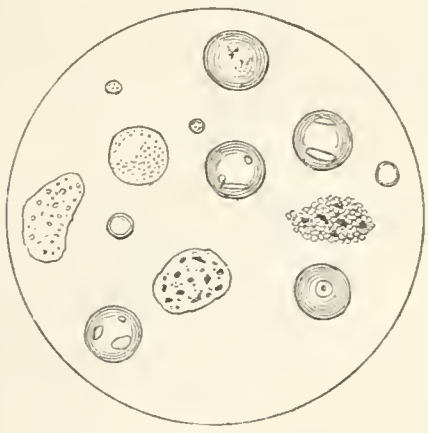

Fig. 3.

lowed by fever and sweating. Spleen enlarged. The red corpuscles contain pigmented bodies, and very small, round, opaque bodies lying in vacuoles, and there are also present a few rosetted and one flagellated body. The white corpuscles contain pigment.

Fig. 4.

October 17th.—He has a paroxysm every day. The blood-changes are the same, except that a few crescents have appeared. The other cases of intermittent fever present the same blood-changes, the stage of development of the organisms corresponding to the length of time which had elapsed since the invasion.

Fig. 5.

Case II.—J. B—— (September 3, 1891). He has had intermittent fever every fall for the past six years. Every day he has had a chill, fever, and profuse sweating, accompanied by vomiting and pain in the head, back, and limbs. Blood-changes as in Fig. 5.

Case III.—A. C—— (September 26, 1891). She had

intermittent fever in the West Indies six years ago. Present attack commenced three weeks ago. Every day she has a feeling of numbness of the entire body, followed by fever and sweating. The blood-changes are like the preceding, except the pigment; white corpuscles are more numerous, and there are also small, round, pigmented bodies free in the plasma.

Fig. [illegible]

Case IV.—J. M—— (August 18, 1891). Yesterday the patient had a severe chill, followed by fever and sweating. There were also pains in the head, back, and limbs, nausea, and vomiting. The red corpuscles contain pigmented bodies, and the white ones pigmented grains.

Case V.—D. O'C—— (August 20, 1891). Present illness commenced two weeks ago. Slight rigor each day for the first few days. Patient feels very weak; complete anorexia. Temperature, 101½° F.; pulse, 120. Very sallow and anæmic. Spleen enlarged. Constant headache. Blood-changes like Fig. 6.

Case VI.—T. R—— (August 27, 1891). Present sickness is of two weeks' duration, and is almost identical with the preceding, except that every afternoon he has intense neuralgic pains in all parts of his body. Blood-changes like that shown in Fig. 6.

The third set of cases were very common, and included all the forms of malarial poisoning which occur in dispensary practice.

The intermittent type occurred most frequently. I have recorded twenty-four cases. Of these eighteen were of the quotidian, five of the tertian, and one of the quartan (?). In these cases both species of organisms existed in the blood, and the stage of development varied with the duration of the cases; but the pigmented organisms, as a rule, greatly predominated over the others. The histories are the ordinary ones, and are like those of the intermittent type in the second set of cases.

The remittent cases were three in number, and of a more severe type. The blood-changes were well marked, and the proportion of the non-pigment organisms were larger than in the intermittent cases. All of these cases begin as intermittent ones, and the paroxysmal character continued through their entire course.

In the chronic and irregular cases the detection of these organisms in the blood of the patients is of the greatest value, as it enables us to make a positive diagnosis in otherwise obscure cases.

Case I.—F. F—— (October 8, 1891). Has been unwell for the past eight years. Never had any malarial fever. Constant headache, frequent slight attacks of jaundice, loss of appetite, sometimes nausea and vomiting. Constant dull pains in his back and limbs. Spleen enlarged. Slight anæmia. Œdema of the feet at night.

Case II.—B. McC—— (August 20, 1891). Every day she has attacks of vertigo and chilliness, but gives no other symptoms.

Case III.—P. M—— (August 27, 1891). For the past two weeks the patient has felt very weak. Constant headache, with pain in the back and limbs. Every afternoon he feels much worse, and sometimes he has sensations of cold and heat. Slight jaundice. Spleen not enlarged.

Case IV.—B. D——. For the past three years the patient has had periods during which she has almost every day had attacks of headache, dizziness, bright spots before the eyes, dyspnœa, palpitation, nausea, and occasional vomiting. Well-marked anæmia. Spleen not enlarged.

The conclusions which I have drawn from the above cases, then, are these: That the conditions described as malarial are due to the development of organisms in the blood. That the species of organism is not always the same in all cases, but that the different species often occur simultaneously. That it is due to this difference in species that the clinical difference in type is due. That a change in type is due to the subsequent development of a new species. That in reality we have two, if not more, distinct but often associated diseases, due to distinct but closely allied organisms.

TONSILLOTOMY AND ITS THERAPEUTIC EFFICACY.

By J. M. W. KITCHEN, M.D.,

NEW YORK.

There is probably no other operation, in a small way, which the general practitioner hesitates so often to perform as that of extirpation of the faucial tonsils, though there are few operations in which the result is so completely satisfactory. It is, perhaps, not difficult to understand why this hesitancy exists. Though it may seem a very simple operation to one who operates with any frequency, it may not appear so to one who is not familiar with the procedure. The site of the operation may seem rather difficult of access. In the case of a nervous child, or adult for that matter, who may not be under moral control, it is not an easy or agreeable operation. Then there is the possibility of severe hemorrhage, and the apparent difficulty of controlling it, in the faucial cavity. But if the proper instrument is used, such reasons should not deter the general practitioner from operating. No one but an expert should use a knife around the tonsils, nor, if it be avoidable, should anyone make a clean cut so near as large an artery as the tonsillar is at the base of the tonsil. The lumen of this vessel rapidly decreases in size as it penetrates the tonsil, and if Morell Mackenzie's tonsillotome is used, no fear need be felt that vessels will be severed too near the larger trunk. Cases of alarming hemorrhage usually result from using a keen-bladed knife, or from tearing the tonsil, or part of it, from its bed. The Mackenzie instrument is rather bulky and clumsy, but it is strong and rigid, and there is a certainty in its use that does not pertain to any other known to me. It can be used as a tongue depressor and as a mouth gag. While cutting it partly crushes the vessel, and hemorrhage is consequently less than from a clean cut. With a patient under moral control, a cold or hot wire-snare can be used. In certain cases where a lobe may not have been included in the fenestrum of the instrument the use of the snare or cautery is desirable to complete the excision. But with a frightened, struggling child it would be difficult to operate at all with any instrument other than Mackenzie's without systemic anæsthesia, and that alternative is undesirable. An assistant is not needed where the patient is under moral control if a high-backed operating-chair is used, or other resisting backing to the head is provided that will prevent the jerking back of the head at the critical moment when severing the tonsil. In nervous cases, and with children, it is desirable to have an assistant hold the head and press the tonsils toward the median line from without. Very young children should be wrapped in a sheet and be firmly held in the lap of the assistant. Cocaine may be used, though the cutting is not very painful, most of the discomfort resulting from the pressure in the fauces

of the bulky instrument while crowding it over the tonsil. Cocaine is useful to shrink very large tonsils to the calibre of the instrument's fenestrum, but is a disadvantage when the tonsils are small; for, as a rule, it is difficult to take away enough tissue in making the cut. With the Mackenzie instrument one need never be afraid of removing too much. It is desirable to operate by artificial light reflected from the forehead mirror; but in that case the operator must be familiar with the use of the head mirror, and be able instantly and automatically, to follow every motion of the patient's head with the directed illumination during the few seconds consumed by the operation. Unless ambidextrous, operate first on the side of the least dextrous hand. Inserting the instrument with one hand, the cutting blade being retracted, use the first and middle fingers of the other hand to depress the tongue and to crowd the fenestrum of the instrument over the tonsil holding it in place, pressing the instrument outward as far as possible. Then, seeing that the blade of the instrument is held parallel with the antero-posterior and perpendicular lines, with the thumb press the blade firmly, and rather quickly, through the tonsil, which will generally be found clinging in the fenestrum on withdrawal of the instrument. Then, without giving the patient time to bewail his woes, firmly and decisively command him to open his mouth, and then excise the opposite tonsil. Always have a large pitcher filled with water and finely cracked ice previously provided to control hemorrhage. I have never had a case that could not be controlled by taking large mouthfuls of finely cracked ice in the mouth, and allowing it to come freely into faucial contact. Sometimes bleeding should be encouraged by free gargling with hot water. Although dangerous hemorrhage is rare, its possible occurrence should always be borne in mind, and its control by pressure or torsion be provided for. Pressure with prepared styptic cotton or other textile substances is efficacious, but astringent powders or solutions used alone are an ineffective nuisance as a rule. Antiseptic cleansing of the throat during healing is desirable, especially if diphtheria is prevalent.

I believe that all who have had any wide experience in excising tonsils will agree that only good can result from a properly performed tonsillotomy. The tonsil may have some beneficent function. It certainly tends to prevent the spirit of many mortals from becoming too proud, for a succession of attacks of quinsy, or even of follicular tonsillitis, can do a great deal in the way of undermining the general health, as well as in inflicting much suffering; but I have never known of a case where the system appeared to suffer from the loss of these bothersome bits of tissue. Granted that the tonsil is a large lymphatic gland and that it does a good work in manufacturing scavengering leucocytes, one is tempted to classify it with the vermiform appendix, corns, birth marks, warts, and such like additions to the body that could be dispensed with easily, and with satisfaction to society in general. I have heard of cases having sore-throats in after years which were attributed to loss of the tonsils, that would in all likelihood have suffered greater ills if these bodies had not been extirpated. As a matter of fact, the presence of these abnormally large masses of tissue in the throat draws excessive amounts of blood and nerve-attention to surrounding parts as well as to themselves. I have heard voice instructors, who should have known better, claim that the tonsil is a muscular organ of great importance to voice production, and that its removal seriously injured the voice; yet many an impaired voice has been restored to its normal excellence by the removal of enlarged tonsils. This operation does not prevent or cure every throat ailment. It will not entirely prevent those due to diphtheria, scarlet fever, measles, la grippe, syphilis, malaria, exposure to cold, etc., though an improved tone in the tissues of the throat, due to the operation, will be helpful in preventing some of those disordered conditions. However, the operation will almost entirely prevent attacks of follicular, as well as peritonsillar inflammations. Septic contamination is, with little doubt, an essential factor in these troubles, especially in phlegmonous tonsillitis (quinsy), and the cicatrized surface of the stump of an excised tonsil is apparently a successful barrier to the entrance of such germinal matter. I have in a number of cases removed one tonsil from patients, and in every case these same individuals have returned and had the other removed because they found immunity from tonsillar affections on the excised side, while they continued to have trouble on the unexcised side.

For several years I have resorted to this operation to abort attacks of quinsy, and, so far, always with success. This practice is contrary to what I was taught, and what, so far as I know, is still taught in the books, which say wait until after inflammation has subsided before operating. My practice is to operate at the beginning of an attack, before the fauces and neighboring parts have become too swollen. It aborts that attack, and prevents others in the future. If the practice were general it would save a great many hours of agonized suffering to humanity. Free incisions will sometimes abort an attack, but more frequently fail. Here is an additional list, probably incomplete, of what this operation will remedy: Anæmia, chorea, and other effects due to insufficiently aerated blood; noisy respiration, snoring, cough peculiar to the condition, impaired voice and articulation; shortness of breath, palpitation of the heart, and spasm of the glottis; broken sleep, nightmare, difficulty in swallowing, bad breath, disturbances of digestion, and impaired taste; mouth-breathing and facial deformity; hypersecretion of mucus and post-nasal catarrh; impaired nasal respiration and hearing; sometimes local pain, follicular pharyngitis and laryngitis.

ELECTRICAL INJURY FOLLOWED BY DELTOID PARALYSIS AND TRAUMATIC NEUROSES.[1]

By JOSEPH COLLINS, M.D.,

NEW YORK.

The following case, presenting as it does the history of a paralysis resulting, perhaps, from an electrical current, and followed by a rather complete functional palsy, is thought of sufficient interest to warrant reporting it.

M. F——, thirty-one years of age, by occupation foreman of a gang of telephone wire linemen. On September 23, 1890, while standing on a telephone pole repairing a trunk wire, he received a current from an improperly insulated electric wire which was fastened to the pole above, and had sunken so that it came in contact with the wire he was repairing. In his opinion—and he is a practical electrician—a current of more than a thousand volts passed through his body, the points of contact being on the inner side of his left leg and the left side of the neck. It was a close, damp day, and as he was perspiring profusely this probably favored better conduction. He thinks about three to five seconds elapsed before losing consciousness, and during this time he says he could distinctly hear the revolutions of the generator, nearly half a mile away; he suffered no pain, only a sense of being filled with something, and a feeling that when that sensation ceased he would die. As soon as he lost consciousness he fell a distance of twenty-five feet, striking a butcher's cart in his descent between the wheel and the body, falling on his side, and then he tumbled to the ground landing on his head and neck.

A few minutes after falling he regained consciousness sufficiently to know what had happened, but remained in a dazed condition for several hours. He was taken to the Presbyterian Hospital, where, he says, a diagnosis of dislocation of the shoulder and fracture of the clavicle was made. The next morning he left the hospital for his home, where I first saw him. The patient was in bed, his mental condition very clear, no particular evidences of

[1] Read before the New York Neurological Society, November 4, 1891.

the shock, and he complained of nothing save his neck and side. The Sayre plaster dressing for fractured clavicle which he had on had been applied at the hospital the previous evening. On examination a severe burn, about as large as the palm of the hand, was found on the left side of the neck just behind the sterno-cleido-mastoid muscle; below and behind this was a large ecchymosis; over the spine of the scapula was another contusion, and on the left side, extending from the fifth or sixth rib to the crest of the ilium, was one large contused wound. A burn somewhat larger than the one on the neck was found on the postero-internal surface of the tibia at its upper third. On removing the plaster dressing the contour of the shoulders seemed to be normal, save a dropping or slight flattening of the left shoulder. No good evidences of fracture could be obtained, and the patient was able to execute most of the movements of the arm in a limited way, with the exception of extending the arm outward, a movement brought about by the muscles supplied by the circumflex nerve. The general condition of the patient was good, except the ordinary concomitants of traumatic fever.

The arm was kept at rest for some days while the wounds were being treated, and anodyne poultices were applied over the shoulder and clavicle to relieve pain. After the burns had healed the muscles were tested for electrical reactions. The muscles tested responded normally, with the exception of the deltoid and teres minor. These with the galvanic current gave slightly increased contractions with the negative pole, and slightly decreased with the positive pole; both contractions incited slowly at the make and break of the current. Faradaic excitability was almost entirely absent. This condition continued unchanged for about three months, except that the excitability to the galvanic current continued to increase for the first five or six weeks, and then to diminish. That is, the number of cells required to cause contraction in the affected muscles continued to become less than the number required to cause contraction on the normal side. After this period the galvanic irritability began to decrease simultaneously with the apparent atrophy of the muscles.

About this time the patient began to complain of numbness of the entire left side, and his leg felt as if made of wood, and a feeling as if the entire left half of the body was paralyzed. Vision with the left eye was obscure, although there was no limitation in the visual field, and no changes could be found in the fundus ophthalmoscopically. The sense of smell in the left nostril was almost entirely absent, as was the sense of taste from the left side of the tongue. The thermal and muscular senses were also somewhat impaired. Sense of touch blunted in parts of the left extremities, but these seemed to be anæsthetic areas, otherwise the sense of touch was normal, but not acute. He complained of being fidgety, nervous, easily frightened, in constant dread of something going to happen, and he thought his mind was not quite as clear as it should be; but the symptom that gave him most trouble was the inability to sleep. The insomnia was very persistent, and none of the many hypnotics tried seemed to have any effect, with the exception of opium; but the administration of this drug was followed by exacerbations of the other symptoms. His bodily nutrition and functions at this time were in excellent condition, and indeed, while presenting this symptom complex he was gaining in weight.

This condition persisted for several weeks, the electrical reactions remaining about the same, with a continuance of the decrease of excitability to the galvanic current and a complete absence of the faradaic irritability, that is both a quantitative and qualitative change.

The ordinary therapeutic measures for the cure of the neuritis were resorted to—such as poultices, in the early stages, and later counter-irritation in the shape of iodine, and by small blisters, and the internal administration of arsenic and iodide of potassium. The hysterical phenomena continued, however, unabated, medicines and suggestions being of no benefit apparently, until in sheer despair it was decided to hypnotize him. The condition of hypnosis was brought about at the first attempt, by fixing his attention and suggesting that sleep should take place. He was carried in the hypnotic state as far as what Liebault calls the fifth degree, that is, a condition of light somnambulism wherein the patient remembers what has passed in a hazy sort of a way, where they have memory of certain things that have been said or done to them, while for others it is entirely lost. During the hypnotic *séance* the symptoms referable to the hysterical condition entirely disappeared. That is, he could hear a whisper in one ear as well as in the other, salt placed on the left side of the tongue was quickly detected, etc. It was then suggested to him that he would sleep soundly that night, and that these symptoms should all disappear, and he was positively assured that he would awaken on the following morning entirely free from his troublesome conditions. The *séance* lasted about ten or twelve minutes, and when he was allowed to come out of it he manifested a sense of forgetfulness as regards his whereabouts, and could only tell in a vague sort of a way what had happened. He was languid and drowsy for a few hours following, but after this had disappeared he began to feel better. The next day, when he presented himself the hysterical symptoms had vanished, and he related that he slept fairly well, without the use of any hypnotics, so that now all that remained was referable to the diseased condition of the circumflex nerve. About five months after the injury faradaic irritability began to be manifested in a small way in the deltoid muscle, and galvanic irritability also seemed to be on the increase, and these phenomena continued to improve, until the response to the electric current seemed to be almost normal as contrasted with the opposite side.

The patient, however, was unable to raise the arm from the side, and he had some trouble about rotating it outward. There being no good grounds for this disability, it was decided to hypnotize him again to determine whether or not a hysterical element was present in keeping this up. The state of hypnosis was brought about as before, it was suggested to him that he had the ability to raise his hand above his head, and he was commanded first to raise his right hand and afterward his left. This was done very quickly with the right, and then slowly he began to raise the left till the arm was at a right angle with the body, the patient groaning and becoming red in the face, and otherwise manifesting sensations of pain meanwhile. It was then suggested to him that he would be able to raise the arm the next day, and then allowed to pass out of the hypnotic condition. But on the following day he complained of pain and soreness about the shoulder, which was probably due to the breaking up of the adhesions arising from the long disuse of the shoulder-joint. The treatment by electricity was continued, and in about a week he was hypnotized with better results than before; that is, from this time onward he was able to use his shoulder muscles fairly well, and in nine to ten months after the receipt of the injury he was able to resume his occupation. Unfortunately, at this time, prolonged and excessive drinking of liquor impeded the rapidity of his complete recovery, but at the present time he is in good condition, with the exception of a certain amount of unwieldiness about the left arm and clumsiness of the left hand, and a feeling that the left side does not correspond exactly to the right.

The case brings up for consideration several interesting questions. First, did the passage of such an intense electric current through the left half of his body cause the injury to the circumflex nerve? and if so, why should this nerve be singled out while the others remained free? It is not at all improbable that electrical injury can cause neuritis as well as other physical irritants, if sufficiently localized and intense; but contact with the current was above the cervical plexus, and even if the injury had been received over the origin of the circumflex, the anterior

branch of the seventh cervical, its other division, the musculo-spiral, must also suffer ; but this nerve was apparently uninjured. Inquiry or discussion on this point would be futile, as there is no way of positively settling it ; however, it seems much more rational to believe that the traumatism resulting from striking on the cart-wheel was the probable cause of injury to the nerve, as the contused appearance of the shoulder and the extensive ecchymosis showed that he must have struck very heavily. Another interesting question is from a medico-legal point of view. This man has instituted a heavy suit for damages against the electric light company, claiming absolute loss of time for nearly a year and some permanent disability, as he avers that he is incapacitated from pole-climbing by a feeling of dread and unsteadiness. Granting that this condition is largely a neurosis, for the electrical reactions of his muscles are normal, can not the patient conscientiously claim that this condition is the direct sequence of his injury and is wholly beyond his control, and would never have resulted if not for the injury, as there is not the least neurotic trouble in his previous or family history. A point in his symptomatology that I would call attention to is the absence of limitation in the field of vision that has been so emphasized in cases presenting a symptom complex somewhat similar to this patient. Professor Schultze, of Bonn, has recently laid stress on the fact that, in several cases of traumatic neuroses that have come under his observation, this symptom was absent in the great majority.

As regards the method of treatment employed for the paralytic condition, it is not my purpose to enter into a discussion as regards the therapeutical effects of hypnotism, or as regards the probable ways by which it is brought about. Whether it be due to brain exaltation, or a psycho-physical transmission, or a direct physical or psychical action, the fact still remains that the condition can be brought about, and in some cases at least in hypnotism we have a measure that may, when properly and conscientiously used, be productive of an immense deal of good when all other therapeutical means fail.

It would probably be well for us as physicians, and for humanity in general, if we would cease to make use of the term hypnotism ; so many people are apt to associate it with the mystic and supernatural, and to employ the term mental or psychical suggestion instead ; for even the relation of this one case goes to show that any benefit that may have been derived from it, was brought about by suggesting to those cerebral areas which preside over the automatic part of inaugurating motion, which had been for so long a time dormant, to bring about movement ; suggesting to, or stimulating those areas, while the parts concerned in higher functions were held in abeyance.

In this country, at least, we are fortunate in not having hypnotism carried to the extent of charlatanry that it is in European countries. And no one who has not looked specially into the matter can conceive of the immense deal of harm done in a city like Paris, alone, where, as Björnström relates, there are more than five hundred establishments with branches throughout the country, all doing a prosperous business and carrying this branch of therapeutics into disgrace.

The length of time elapsing between the receipt of the injury and the recovery of the functions of the nerve and muscles is apparently shorter than that ordinarily given in the authorities on traumatic neurosis; but it must be remembered that the circumflex nerve is comparatively short, and not far distant from its ganglion, and these factors, in conjunction with the reparatory powers of the body, are in all probability of the greatest importance in determining the length of time taken in the reparatory process.

Monochlorphenol is recommended by Dr. Passerini for inhalation in phthisis.

Ether Drinking is becoming fashionable in Paris, where it is taken with brandy, half and half.

Progress of Medical Science.

Acute Miliary Tuberculosis and Meningitis. — Dr. Reinhold (*Deutsche Archiv für klin. Med.*, 48, 1891) says that the irregularities in the technical curve without corresponding modification of the other symptoms in the typhoid form of acute miliary tuberculosis is, in doubtful cases, a point in favor of tuberculosis and against typhoid. A considerable acceleration of the respiration usually precedes quickening of the pulse. The absence of splenic tumor is also a strong argument for miliary tuberculosis, as is also the presence of small crepitant and sub-crepitant râles here and there without dulness or souffle. In the broncho pulmonary form the discovery of bacilli must not be relied upon for the diagnosis. It is better to seek for the origin of the disease in some local tuberculosis, infiltration of the apex, tracheo-bronchial adenopathy, or cheesy desposit in the kidney with purulent urine ; all of which favor an acute tuberculosis. Tubercles of the choroid is only a late manifestation.

Complications of the Grippe.—Johannsen has seen an acute nephritis after influenza in a man of fifty-two, followed by a paralysis of the right arm with cold and cyanotic surface, in which recovery took place in twenty-four hours. A similar condition attended with severe pain then took place in the right foot and gangrene followed. Amputation became necessary and it was then found that the veins were filled with extensive firm thromboses. It was believed that the same condition had been present in the arm. Another case is related of a young girl of fifteen, who a few days after recovery from the grippe was taken down with a phlegmasia alba dolens of the knee. The case threatened to prove of a severe type but ended in complete recovery.—*St. Petersburg Med. Wochensch.*

A New Clinical Form of Diabetes is described by Hirschfeld (*Zeitsch. f. klin. Med.*), which is characterized : 1. By violent attacks of colic which occur in the early stages of the disease but cease subsequently. 2. By a urine but slightly increased in quantity, and consequently often depositing sediment. 3. By a white color of the fecal matters without fatty masses being discoverable in them. In this form the absorption of fatty and albuminoid substances is much diminished, instead of remaining about normal, as in ordinary diabetes. The clinical march, in consequence of troubles of nutrition, is ordinarily rapid and grave. One of the principal therapeutic indications is a diet containing albuminous materials, in particular fatty matter and alcohol.

Lysol, the new disinfectant and antiseptic, is recommended as promptly arresting the development of micro-organisms. Cramer, Wehmer, Michelsen, and others have successfully employed it in surgery and gynecology, and Hænel says it is an unusually agreeable agent for the operator. Unna has used it as a plaster mull in various skin affections, and Phillips has tried it with some success in lupus. It has also been advised in rhino-pharyngeal and laryngeal disease, as well as in affections of the middle and external ear. It is obtained by dissolving the fraction of tar oil, which boils between 190° and 200° C., in fat, and subsequently saponifying with alcohol. It is a clear, brown, oily liquid, and contains fifty per cent. of cresols. It can be mixed readily with water, and forms clear solutions with glycerine, alcohol, chloroform, and various other fluids. Fuerbringer recommends half to one per cent. solution for the hands, and one quarter per cent. for instruments. It is only one-eighth as poisonous as carbolic, and cheaper. Pée recommends a one per cent. solution in midwifery and gynecology, and says that a 1 to 200 solution destroys streptococci in fifteen minutes. His experience with it has been very favorable.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., Nos. 56 and 58 Lafayette Place

New York, January 16, 1892.

THE FINANCIAL SIDE OF THE QUESTION.

WE have often had occasion in these columns to refer to the money side of medical practice, for we think that is the side which the physician is too apt to neglect, his energies being devoted rather to the scientific and philanthropic aspects of his work. This is very right and proper in moderation, for the physician is primarily a scientist who labors for the good of his fellow-man, and whose first thought is ever for the relief of suffering and the saving of life. But this is not all. We have not yet reached the millennium of the socialists, and the State supports only a comparatively small number of its citizens, leaving the rest to find their own living by their brains or their hands, as each one is best fitted. The physician, therefore, while devoting himself to his fellow-man, giving him his time, the results of his study and experience, and the product of his best mental and physical labor, must also look to that fellow-man for his support. The laborer is worthy of his hire, and the medical man is entitled to a just compensation for his labor. But how often does he get it? That he does not get it as often as he should is only too evident, but what is not so evident perhaps, yet none the less true, is that it is our own fault and the fault of our predecessors that our services are never so readily paid for as the lawyer's, or even the clergyman's.

In a book recently published by Dr. J. J. Taylor,[1] the author goes into the causes for the condition that prevails, and suggests certain remedies for its relief. "It is a well-known fact," he says, "that however useful and indispensable the medical profession is, yet doctors are, as a rule, financially poor men. There is no class of men with an equal amount of capital invested, of equal intellectual force and scientific culture, and devoting an equal amount of time to business, who realize so little for themselves and families as medical practitioners. Painful examples are occurring all over the country, in crowded cities as well as in rural districts, of men eminent in scientific attainments, rich in a record of skilful activity and noble deeds, after a life of enthusiastic devotion to the relief of suffering humanity, finally passing away and leaving their own loved ones most inadequately provided for to meet the demands of every-day life."

[1] The Physician as a Business Man; or, How to Obtain the Best Financial Results in the Practice of Medicine. By J. J. Taylor, M.D., Philadelphia. The Medical World, 1891.

Some of the causes the writer finds in the unselfish principles underlying professional life, which forbid the practitioner to patent any instrument or to keep secret any therapeutic measure. Then the physician's sympathy for the suffering, and his absorbing interest in the scientific aspects of his cases, raise his mind above financial considerations, and cause him to forget that he is working for the support of himself and his family, as well as for the good of humanity. The physician has furthermore, as a rule, an inborn repugnance, or at least incapacity, for money-making pure and simple. He dislikes more than anything else the financial relations between himself and his patients, and he would gladly, like a surgeon quoted by Dr. Taylor, treat every and all patients just as they came, without a thought of the fee, if he could only be guaranteed an income sufficient to supply the present and future needs of his family. The public appreciates the fact that "there is no money" in medicine, and therefore the born money-makers avoid the medical profession instinctively, choosing for their life-work some occupation in which the chances of riches are greater. Owing to this shrinking from even the appearance of being mercenary, the physician often hesitates to prosecute his just claims, even when he knows that his patients can pay. Among other causes are the crowded state of the profession, and the resulting over-active individual competition, and also the unscrupulous and cruel competition of the swarm of dispensaries, clinics, and hospitals whose managers strive only for numbers, giving little heed in many cases to the financial circumstances of those who apply for relief, nor refusing to care for those who may be perfectly able to pay for medical attendance.

The remedy lies with the physician himself. He must school himself against the sentimental side of his work, and must cultivate business methods and habits. He must recognize the value of his own services, and must make his patients recognize it. It is often said that a man is valued according to the price he puts upon himself, and this is true in the good sense. If a man shows himself always ready to respond to every call, but never ready to demand a reward for his services, it will not be long before his patients become equally careless, and neglect to pay the bill when it is presented, reasoning that the doctor cannot need or care for his pay if he shows so little energy in getting it.

There is no reason why a medical man should not conduct his practice on business principles—indeed, there is every reason why he should do so. There is nothing derogatory to one's dignity in endeavoring to obtain as much as he can for his services, whether those services be in saving the property or life of a man in a court of law, or in restoring the health or saving the life of a man attacked by disease. The medical man must be a business man. He should do the very best he can for his patients, devoting to their service his time and his knowledge, and then he should make them pay for the attention, and pay well. Let his charges be as high as is consistent with the service rendered and the circumstances of the patient, and let him see to it that he is paid. If the physician appear indifferent about his pay he may depend upon it that the patient will be at least equally indifferent. Bills should be rendered promptly,

and should be followed by a reminder after a reasonable period if payment is delayed. And when necessary, if the patient is known to be able to pay, he should be forced to do so by legal methods. And here comes in the necessity of accurate book-keeping. Charges should be entered in the books at the time they are made, and the accounts should always be kept in such a shape that they may be offered as evidence in case it becomes necessary to sue a delinquent patient.

The little book from which we have quoted contains much that is interesting, and much that is practical, and should stimulate the careless to pay more attention to the business side of their profession. If physicians would insist upon a just compensation for their labor and their advice, they would not only better their own financial status, but they would also enhance the dignity of their profession. The average man values a thing at what it costs in money to get it, and when he finds that he can secure medical advice only by paying for it, he will learn to value it more highly, and his respect for physicians individually, and as members of a dignified profession, will be proportionately increased.

There is altogether too much free work, both in private and in public, done by medical men, and it is time they learned to take better care of themselves and of their families.

PATHOLOGICAL ANATOMY OF INSANITY.

In the *Journal de Médecine de Paris*, March 1, 1891, Dr. Luys states that in examinations of brains of patients suffering many years from excitement, there is hypertrophy of certain special regions of the paracentral lobules. These lobules are the point of confluence of cortical psycho motor convolutions and one of the regions where accumulate specially psycho-motor innervations. Hypertrophy would, therefore, indicate a focus of continued excitation, absorbing undue vitality, and leaving other regions to undergo more or less marked atrophy. This hypertrophy is usually symmetrical in both hemispheres. In the brain of a woman who had a visceral delusion, that was almost her sole idea, to the effect that a tape-worm found a lodgement within the internal organs and came and went at pleasure, there was unilateral hypertrophy of the paracentral lobules, those in one hemisphere remaining perfectly normal. The patient was perfectly lucid and rational on all subjects, except this one delusion, though it was difficult to induce her to speak of any other. Anatomically, Dr. Luys explains the coexistence of clearness of mind and a delusion. She was insane in one hemisphere of the brain and sane with the other. For such cases, the colloquial term "unbalanced" would seem to be literally true.

THE SCALENUS.

There is something novel and refreshing in the development of an acrid discussion over the scalenus muscle. We have always felt a certain degree of attachment to the scaleni (as they have to us), because they never lay so deep in the neck as to make their dissection tedious and difficult. We are glad, therefore, to find these muscles rising into controversial prominence. English and German anatomists count three scaleni muscles; the French have been content with two, but are now preparing to reduce this number to one, which accords, we believe, with the views of the old anatomists. M. Sebileau says that the scalenus starting above as a single muscle splits below in order to give passage to the brachial plexus and the subclavian artery. He adduces as proof of his contention the following reasons: 1. The uniformity of the insertion of the scalenic mass. 2. The frequent existence of anastomotic fasciculi between the anterior and the posterior scaleni. 3. The splitting sometimes observed of the anterior scalenus for the passage of the subclavian artery. 4. The passage in certain subjects of the brachial plexus through the scalenus posticus. 5. The fusion over the pleural dome of the pleuro-transverse muscle and the costo-pleural ligament. M. Sebileau regards the scalenus muscle as a group of intercostal muscles. It is, in fact, a *long cervical intercostal*, being inserted at both ends into ribs, above to the anterior tubercle of a transverse process —a rudimentary rib.

THE DOCTOR AND THE PRIEST.

Not long ago a controversy arose over the sick-bed of a woman in a neighboring city, between the attending physician and the spiritual adviser, which seems to call for a few words. Unfortunately, it was not the first time that similar disputes have arisen, and doubtless it will not be the last. The facts of the case, as far as they can be gathered from the newspaper accounts, are as follows:

The physician was called in the middle of the night to see a woman suffering from post-partum hemorrhage. While he was at work endeavoring to arrest the hemorrhage, the patient's spiritual adviser, a Catholic priest, who had been summoned by the relatives, arrived. He was met by the husband, who told him that the doctor was still engaged with the patient, but would probably be through in a short time, and that he could then administer the rites of the Church. The priest would permit of no delay, and insisted upon seeing the woman at once. It would take but a few moments, he said, to receive the woman's act of contrition, and even if her life was still jeopardized by the interruption of medical treatment, it was nevertheless the duty of the husband to give the spiritual adviser precedence at such a time. The welfare of the soul, he insisted, was of so much greater importance than that of the body, that it was better for one to take the chance of losing his life than to run the risk of dying without absolution. The doctor, on the other hand, refused to leave the bedside of the woman, as her condition was very precarious, and he feared that to abandon her at that time might result in her death. The end justified him in the stand he took, as the hemorrhage was finally arrested and the woman's life was saved. On the following Sunday the priest addressed his congregation from the altar, telling them that they ought to employ only Catholic physicians, who would see to it that they received the ministrations of the priest when they were dangerously ill, and added that he had been hindered in his work by Protestant physicians.

We can appreciate the position which the priest took, and believe that he acted in perfect good faith, and was actuated solely by a desire to promote the woman's spir-

itual welfare, and not by any wish to take precedence of the medical adviser. Yet he was wrong. The physician was actively employed in trying to arrest the hemorrhage, which, if uncontrolled, would cause the patient's death; and if he had abandoned her for ever so short a period at that critical time a life might, and probably would, have been sacrificed. If he had not succeeded in arresting the bleeding from the uterus, when he saw that death was inevitable, then it would have been his duty to make way for the clergyman. The ministrations of the priest could be postponed without prejudice to the woman's spiritual welfare, but those of the physician could not be put off without imminent peril to her temporal existence. Clearly, then, the doctor was in the right, and he would have been unworthy of his calling, whatever his religious convictions might be, had he abandoned his patient at such a critical period for any consideration whatever. It is, of course, the duty of the physician to respect the religious beliefs of his patients, and to warn their relatives of the danger of death, in order that they may call in the priest, if they are Catholics, and so desire. And we believe any true physician, be he Catholic, Protestant, Israelite, or agnostic, would do so, and would oppose any obstacle to the free intercourse of priest and penitent. But he cannot allow anyone, priest or parent, spouse or child, to separate him from his patient when it is a question of life or death. His mission is to save life, and he would be recreant to his calling, and well-nigh a slayer, did he desert his patient in the moment of peril.

The priest may have thought it was his duty to denounce the physician publicly during the celebration of religious services, but the ordinary simple layman cannot so regard it.

Meanwhile we congratulate the patient, who was the involuntary cause of the controversy, for she is still in the and of the living, and can now go quietly and calmly about the important duty of preparing herself for any future emergency.

The Annual Report of the Surgeon-General of the Navy, Dr. J. Mills Browne, for 1891, has appeared. From it we learn that only four vacancies now occur in the medical corps. The Museum of Hygiene has done some work, but its progress is hardly commensurate with the importance of the work it undertakes. There have been 1,796 books and pamphlets added to the library and 126 new exhibits to the museum. The death rate in the navy was 9 in 1,000. The number of sick in hospitals was 88.51 per 1,000. A large number of valuable reports on the medical and sanitary condition of the various vessels, hospitals, and stations are embodied and included in the volume.

Medical Inspection in the Public Schools.—The Boston School Committee have recently passed an order that the request of the Board of Health to appoint a number of medical inspectors of the schools be granted, the School Board assuming no responsibility. The object and plan of this system of inspection will be found on page 360 of the *Journal* for October 1st. This system may at present be said to be experimental. Fifty physicians will be appointed, and the inspection of the schools will probably begin on the first of the year.

News of the Week.

World's Fair Committees have been appointed by the several societies to act conjointly with reference to medical matters, and some outcome is patiently awaited. A very busy and progressive man, Dr. Charles Warrington Earle, has the matter largely in hand, and will, no doubt, continue its vitality.

The Death of Dr. Van Wyck.—The following resolutions upon the death of Dr. William H. Van Wyck were passed at a meeting of the Medical Board of Charity Hospital, held January 2, 1892:

"*Whereas*, The Medical Board of Charity Hospital has heard with profound sorrow of the death of their colleague Dr. William H. Van Wyck, which occurred on November 16, 1891.

"Dr. Van Wyck was one of our oldest members, and was endeared to us all by his geniality and kindliness of heart. He was an esteemed member by reason of his broad knowledge of medicine and of surgery, and of his rare talents in practical therapeutics.

"The members of the Board, therefore, hereby express their great grief at the removal of their esteemed colleague by death, and extend their sincere sympathy to the widow, relatives, and friends of the deceased, with the assurance that they will ever cherish his memory.

"*Resolved*, That an engrossed copy of this tribute to the memory of Dr. William H. Van Wyck shall be sent to his widow, and that copies shall also be sent to the home medical journals.

ROBERT W. TAYLOR,
HENRY GOLDTHWAITE,
THOMAS H. BURCHARD,
Committee.

"By order of the Board.

WILLIAM C. JARVIS, M.D., *Secretary.*"

Dr. Paul Mundé was elected a Corresponding Fellow of the Obstetrical Society of Leipzig, at its four hundredth meeting, on October 19, 1891.

The Contagiousness of Influenza is believed in by many physicians. Dr. J. R. Leeson (*Lancet*) describes how he prevented an epidemic in an asylum by isolation. The incubation, he thinks, is about five days.

The Bacillus of Influenza.—The cable states that Dr. Peifer, son-in-law of Koch, has discovered the bacillus of influenza.

The Law Against the Practice of Hypnotism Declared Unconstitutional.—The Court of Appeals in Brussels has recently had before it a case where three persons had been sentenced to eight years' imprisonment for having practised medicine, illegally employing hypnotism for the cure of various affections. Much to the surprise of the medical profession, the appeal was allowed, and the prisoners were discharged.

A Prolific Mother.—A woman in this State, thirty years old, married eight years, has given birth to fourteen children; viz., triplets three times, twins twice, single birth once. Only four children are now living.

Dr. Joseph Hilton, of this city, died on January 7th, aged seventy-six years.

The Paris Society of Medicine offers a prize of 1,500 francs and a gold medal for the best essay on tuberculosis, to appear before the end of 1892.

Dr. Wilhelm Krause, who has been Extraordinary Professor of Anatomy in the University of Gottingen for thirty years, has resigned his chair.

Professor Ernest William Brucke, the distinguished physiologist, is dead at Vienna. Professor Brucke was born in Berlin in 1819. He was the son of a painter, but soon turned his attention to physiology, which he studied at Berlin and at Heidelberg. In 1848 he became professor of anatomy at the Academy of Fine Arts in Berlin, and was called to the chair of Physiology at Koenigsberg, whence he went to Vienna in the following year as Professor of Physiology and Microscopic Anatomy.

The Hospital Sunday Collections have been rather meagre this year in this city, as they were in London. Up to date the amount collected was less than $25,000.

Bequests to Hospitals.—A large sum of money has been bequeathed to various hospitals of this city by the late Mrs. Robert L. Stuart. The sums reach $60,000 to $80,000.

Disease at Santos.—The captains of vessels arriving from Brazil bring most alarming reports of the ravages of yellow fever and small-pox in the pest-ridden city of Santos. Eighteen captains of merchant vessels have died, either from the black vomit or small-pox, within two months. On some vessels almost the entire ship's company, officers and crew, have perished from these maladies. Many sailors have died in the streets from yellow fever, so quickly fatal is the disease. It is estimated that at least two-thirds of the persons attacked have died. The great majority of the victims are immigrants and sailors. A much greater mortality than now exists is looked for during the hot months of January and February.

The Pasteur Treatment Failed.—A man died on New-Year's Day in Newburg from hydrophobia. He was bitten in thirteen places by a mad dog on September 19th. He placed himself under the Pasteur treatment, and at the end of a month was pronounced out of danger. A few days before his death, however, one of his arms, which had been bitten, became painful, and death from hydrophobia followed speedily.

Tuberculosis in Workshops.—A physician in Paris found 32 out of 35 men employed in the Electric Lighting Works in Paris were suffering from tuberculosis, 23 of them having become infected since entering the shop.

Removal of the Gasserian Ganglion.—Mr. Rose, of King's College Hospital, recently removed the Gasserian ganglion from a woman, sixty-three years of age, who had for two years suffered from very severe neuralgia of the supra- and infra-maxillary divisions of the fifth nerve. The operation was successful, the patient being entirely relieved from pain. Mr. Rose has performed this operation now four times.

The Prevention of Phthisis.—The Russian Society for the Preservation of the Health of the People, a non-official, but probably more or less officious, organization, has presented a petition to the health authorities of the empire, praying that consumption be declared a contagious disease, that notification of the disease be made compulsory on the medical attendant, that special hospitals be provided for the treatment of phthisical cases, that spittoons containing disinfectants be kept in all public places, and that spitting on the ground be forbidden under pain of fine or imprisonment.

The Marine Hospital Service.—Washington gossip has it that the former director of this service is tired of Chicago and wants his old place in Washington, but that his successor, the present incumbent, naturally wants to stay where he is.

Reviews and Notices of Books.

Records of the Association of Acting Assistant Surgeons of the United States Army, A.D. 1891. Edited by W. Thornton Parker, M.D., Recorder A.A.A.S. Pp. 149. Salem, Mass.: Salem Press Publishing and Printing Co. 1891.

The Association of Acting Assistant Surgeons of the United States Army aims to obtain justice for a much-imposed upon, maltreated set of men, namely, its members. It desires, first of all, that assistant surgeons now in service be commissioned and paid as second lieutenants of cavalry. The book in hand gives a list of members, a history of the organization, minutes of the last meeting, and a record of its members. It is a splendid specimen of the publisher's art, and a handsomer book would be hard to find. The association deserves every encouragement.

Epidemic Influenza. Notes on Its Origin and Spread. By Richard Siseby, M.D., Member of the Royal College of Physicians of London. Pp. 150. London and New York: Longmans, Green & Co. 1891.

This is an excellent and timely treatise on the origin and method of spread of epidemic influenza. It finds its origin, he claims, in a microscopic organism, but where it first appeared is open to argument. The means of spread is contagion. The book is well written, the plates are good, and the author's exposition of the subject is a good and thorough one.

Handbook of Materia Medica, Pharmacy, and Therapeutics; Including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Practical Pharmacy, and Minute Directions for Prescription-writing. By Samuel O. L. Potter, A.M., M.D. Jefferson, M.R.C.P. Lond., Professor of the Theory and Practice of Medicine in the Cooper Medical College of San Francisco; author of "Quiz-Compend of Anatomy and Materia Medica," "An Index of Comparative Therapeutics," and "A Study of Speech and its Defects;" late Acting Assistant Surgeon United States Army, and Brigade Surgeon National Guard of California. Third Edition, Revised. Pp. 767. Philadelphia: P. Blakiston, Son & Co. 1891.

This is an old and valued friend which needs no commendation, much less an introduction. It ought to be in the library of every physician and student. It is the most convenient and most concise work on therapeutics and materia medica in the English language, and is at the same time thoroughly reliable. Though necessarily largely a compilation, nevertheless there is much that is original, the author being one of the most prominent of American therapeutists. The contents embrace the essentials of practical materia medica and therapeutics,

the amount of pharmacy that every physician should possess, one of the best sections on prescription-writing ever written, besides a great mass of interesting and valuable material relating to the subject of the work. Both diseases and remedies are arranged alphabetically, making the book unusually convenient. The section on applied therapeutics includes, besides the writer's own views, the recommendations of fifty authors. All in all, the book is an exceedingly useful one.

A Manual of Practical Obstetrics. By Edward P. Davis, A.M., M.D., Clinical Lecturer on Obstetrics in the Jefferson Medical College, Professor of Obstetrics and Diseases of Children in the Philadelphia Polyclinic, Visiting Obstetrician to the Philadelphia Hospital, etc. Pp. 298. Philadelphia: P. Blakiston, Son & Co. 1891.

This manual is, unlike many of its class, not a mere compilation, but contains a number of practical hints not usually found in larger works. The chapters on the diagnosis of pregnancy, the treatment of normal and premature labor, operative obstetrics, the puerperal state, and post-partum hemorrhage commend themselves especially by their clearness and conciseness. We are glad to see that the writer is a believer in episiotomy, and find on page 81 the only intelligent description of that useful operation which we remember having read. If the advice given in Chapter VI., on the examination of patients before the beginning of labor, were generally followed there would be an immense difference in the maternal and fœtal mortality. Obstetrics will never make any progress in this country until the general practitioner learns to recognize abnormalities before it is too late to save the patient. The chapter on the laceration of the perineum and pelvic floor is a useful one. In such a condensed work much must be omitted. As a serious omission, however, we note the absence of any reference to accidental hemorrhage, an emergency with the phenomena of which every accoucheur should be familiar.

The style is clear and concise, the illustrations helpful; in fact, the work is one which deserves, and will obtain, a wide circulation.

Contributions to Gynecology. Fasciculus I., The Galvanic Treatment of Uterine Fibroids. By Ephraim Cutter, A.M. Yale, M.D. Harv. et Univ. Pa., LL.D. Iowa, etc. New York: William A. Kellogg.

This small volume, with its ponderous title-page and dedication, contains matter both interesting and amusing. Dr. Cutter's work in this direction is so well known that it is unnecessary to dwell upon his method of treating uterine fibroids. Full details of fifty cases are given, with comments. Of these, the growth was arrested in twenty five and disappeared in eleven; seven cases were "non-arrests" and four "fatals." The author is an enthusiast, but we think an honest one. However, comparing his claims with the more modest pretensions of Apostoli, one cannot help saying, "The lady doth protest too much, methinks."

Atlas of Clinical Medicine. Vol. I., Parts I. and II. By Byrom Bramwell, M.D., F.R.C.P. Edin., F.R.S. Edin., Assistant Physician to the Edinburgh Royal Infirmary, etc. Edinburgh: Printed by T. & A. Constable at the University Press. 1891.

This is one of the notable productions of the year. Judging by the parts already issued, the author intends to give to the medical public a splendid and systematic illustrated treatise of clinical medicine. Various forms of art are called into service to give the counterfeit presentment of abnormities described in the text — as photogravure, tinted crayon, and simple black and white, after paintings and photographs from life, now in possession of the author. The letter-press is designed to contain a detailed description of many of the diseases illustrated by the plates; and whenever possible a complete clinical history of the cases figuring in the "Atlas," and articles on medicine, with wood-cut illustrations. Each yearly volume will be complete in itself. Subscribers to the first yearly volume are under no obligation to subscribe to the second or succeeding yearly volumes. The present numbers contain most interesting and instructive papers on myxœdema, Hodgkin's disease, sporadic cretinism, Friedreich's ataxia, Addison's disease, etc., together with plates at once characteristic and impressive, though there is something to be desired in the matter of coloring. The author is a master of style, and offers to the reader a mass of valuable information that is the outcome of erudition and experience, in an English dress at once lucid, direct, and forcible. It is impossible to speak too highly of this valuable work, which must be studied to be appreciated. To the earnest student the "Atlas of Clinical Medicine" is one means toward the acquisition of a liberal medical education, containing, as it does, no word not germane to the subject and every explanation necessary to knowledge and precision.

Essentials of Nervous Diseases and Insanity, Their Symptoms and Treatment. A Manual for Students and Practitioners. By John C. Shaw, M.D., Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School; Consulting Neurologist to St. Catharine's Hospital and Long Island College Hospital; formerly Medical Superintendent of Kings County Insane Asylum. Forty-eight Original Illustrations, mostly selected from the Author's Private Practice. Pp. 194. Philadelphia: W. B. Saunders. 1892.

This is the latest addition to Saunders's excellent series of Quiz compends. It is a primer for advanced students, to be used in conjunction with Edinger's "Lectures on the Structure of the Central Nervous System," and Dr. Browning's monograph on the "Vessels of the Brain." Anatomy and physiology are not much discussed, but for its scope the book is first-rate and of great value.

A Sketch of Surgical History. (After Hecker.) By John Hund, M.D. Pp. 38. Cloth, price 75 cents. Chicago: Ed. Ackerman & Co.

This is a short history of surgery from the time of Herophilis (1500 B.C.) to the beginning of the present century. It is the first work of this kind in the English language, and is both interesting and valuable.

Minor Surgery and Bandaging; Including the Treatment of Fractures and Dislocations, Tracheotomy, Intubation of the Larynx, Ligations of Arteries, and Amputations. By Henry R. Wharton, M.D., Demonstrator of Surgery and Lecturer on Surgical Diseases of Children in the University of Pennsylvania; Surgeon to the Presbyterian Hospital, the Methodist Episcopal Hospital, the Children's Hospital, and the Drexel Hospital for Children; Consulting Surgeon to the Rush Hospital for Diseases of the Chest, etc. With Four Hundred and Three Illustrations. Pp. 497. Philadelphia: Lea Brothers & Co. 1891.

This book covers all that the ordinary works on minor surgery do, and in addition has chapters on amputations, ligations of arteries, tracheotomy, etc. In short, it is also an operative surgery, and a very good one too, its numerous and excellent cuts making the author's text unusually clear. One feature of the book that will make it popular is that part treating of aseptic and antiseptic surgery. Minute details for carrying them out are given, such as the preparation of gauze, silk, and catgut, making various solutions, etc. The author's extended experience as a hospital surgeon gives him especial fitness for writing such chapters, and they are all excellent and entirely practicable by the ordinary practitioner.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, November 18, 1891.

EGBERT H. GRANDIN, M.D., CHAIRMAN.

Case of Vicarious Menstruation.—DR. C. B. KERLEY presented the patient, an Irish girl, aged about twenty-five, who began to menstruate at the age of fifteen. Coincident therewith an abscess appeared about the level of the cricoid cartilage on the left side, which bled, and had bled again about four to six ounces of blood mixed with pus for four days out of each twenty-eight days since the age of fifteen, healing and forming a cicatrix during the intermenstrual periods. The only period of quiescence had been during the carriage of a baby and for four months during lactation, and again, the last menstrual period, when the cicatrix remained intact but blood escaped from the mouth. The patient said the hemorrhage on this occasion was from the throat, beneath the scar, but Dr. Rice made an examination and could find no evidence of this.

DR. C. S. COLE had a case under observation in which when anything, as a cold, interfered with normal menstruation, blood would be found mixed with the urine. He could not yet say whether it was a case of vicarious menstruation from the kidney or bladder, or one of lithæmia or other state giving rise to the hemorrhage.

THE CHAIRMAN had seen, and yet occasionally saw, three cases of vicarious menstruation. In one, the patient, now twenty-eight years of age, there was profuse epistaxis each month and very little discharge from the vagina. The second one menstruated in part from the umbilicus. He had been unable to find an opening, and the inference was the blood oozed from the sudoriferous glands. The third case consisted in hæmaturia occurring, not at every menstrual period, yet at no other time when it did take place. He said that some years ago Dr. Cairo presented a woman who menstruated from a molar tooth. The tooth was drawn by an enterprising dentist, but the patient continued to bleed every twenty-eight days from the cavity where the tooth had been.

Being asked by Dr. Kerley what management he would suggest in the case presented, Dr. Grandin said he would let the case alone so long as no harm occurred.

DR. KERLEY suggested that since at the last period the blood seemed to have come from the trachea, possibly danger would arise in the future.

THE CHAIRMAN was still of the opinion that it was best to wait, for it would be like looking for a needle in a haystack to operate where one knew not what he was operating for. The only suggestion which he could make in the case was to encourage freer flow from the uterus.

DR. KERLEY stated that Dr. Rice had excluded connection between this cicatrix and the thyroid gland.

DR. G. M. EDEBOHLS recalled a case of vicarious menstruation from the stomach, the patient vomiting blood every month. There was double pyosalpinx in this case, but he was unable to say whether the tubal disease had any influence in diverting the menstrual flow from the uterus to the stomach.

DR. WALLACE said that while he was house-surgeon at the Kingston General Hospital, Canada, a patient entered who, instead of menstruating normally, vomited blood monthly. There was only a "show" from the vagina. The os in her case was stenosed, and after it was dilated she menstruated in the normal way during the time she was under observation, which was six months.

DR. EDEBOHLS knew a girl who at each menstrual period had a marked flush on one side of the face over a semilunar-shaped area, which revealed to all her friends the date of the event. She menstruated, however, in the regular way.

A Clinical Record: Ectopic Gestation.—The first paper of the evening was read by DR. C. S. COLE, on this subject. He gave a history of a case of irregular and missed menstruation, colicky pains, and an extra-uterine tumor. The case was seen in consultation by Dr. Grandin, who coincided in the opinion that it was in all probability a case of ectopic pregnancy. The patient was kept in bed three weeks; eight séances of electricity given (galvanic, fifty milliampères), six for fifteen minutes, two ten minutes, at intervals of from one to four days, at the conclusion of which the tumor had disappeared, the uterus had become enlarged, and a normal gestation seemed to obtain. An examination two months later seemed to confirm that opinion.

After reviewing some of the well known cases of this kind, and especially in the light of the case reported, the writer submitted as his conclusion the following propositions: 1. There is considerable, may we not say incontrovertible, evidence that a strong probability of ectopic pregnancy can be determined in the pre-rupture stage. 2. The diagnosis in the pre-rupture stage can, without operation, seldom, if ever, be absolute. 3. We are not justified before rupture in an immediate laparotomy, on a suspicion, however strong, unless there are peculiar and unusual conditions that will not warrant delay. 4. Electricity has proved itself, in intelligent hands, comparatively safe, often efficient, and is, in the pre-rupture stage, worthy of careful trial. 5. We should be prepared to do a laparotomy at any time if rupture supervenes, or if other considerations make operative interference imperative.

DR. VINEBERG thought the paper had covered the ground well. He recalled a case in which the attending physician had had the patient under observation for some time and nothing was present. When Dr. Vineberg examined her he found a tumor the size of a hen's egg, to the left of the uterus, the uterus was found to be slightly enlarged, there were irregular hemorrhages and the tumor just mentioned, and he made the diagnosis of extra-uterine pregnancy. It turned out, however, to be a case of uterine gestation, which the patient got rid of about the tenth or twelfth week.

DR. R. A. MURRAY thought it would be seldom the physician would have an opportunity to make a diagnosis of ectopic pregnancy before rupture, or immediate danger of rupture, for the reason that women seldom consulted the doctor during the first two months of pregnancy. He did not think it absolutely necessary to condemn all cases to the knife as soon as a diagnosis was made. Electricity might be used, but one should hold himself in readiness to resort to laparotomy as soon as any indications for it arose.

DR. H. J. BOLDT thought that in the majority of cases the diagnosis of ectopic pregnancy could be made with considerable certainty. The galvanic current would kill the fœtus, but he thought the patient would run less risk altogether by submitting to laparotomy.

DR. G. M. EDEBOHLS had diagnosticated ectopic pregnancy in three cases before rupture, and believed this was as surely possible as to diagnosticate other pelvic conditions. Before rupture and the third month he would use electricity.

DR. JARMAN referred to Hawley's case, in which an operation was performed before rupture, as evidence of the possibility of diagnosis at this period. Yet, as a rule, the physician was not consulted before the sac had partially or completely ruptured. It had been claimed on the one hand that electricity would kill the fœtus, and on the other, cases had been related in which it had been said to cause the fœtus to descend into the uterus. He could not understand the latter fact, while he might admit the former. In a hospital where they stood ready for laparotomy at any moment, electricity might be used, but he thought the risks were greater under the electrical treatment, without subsequent observation of the patient, than under surgical.

The Chairman made some remarks bearing on the diagnosis in this case, which he felt was as positive of extra-uterine pregnancy in the beginning as could well be short of laparotomy and exposure of the ovum. If there was an error in diagnosis, and if Dr. Cole had opened the abdomen, what would he have found? There was a tumor, but what could have been its nature since, without other treatment than electricity, it had disappeared? Why, if it were an ectopic pregnancy, electricity should not have killed the fœtus he was unable to say. In fact, we knew yet very little about electricity. Perhaps the fœtus, being only about four weeks old, was of such low vitality that it was able to survive fifty milliampères of the galvanic current. The tube, not being over-distended, may not have lost its power of vermicular contraction and expelled the ovum into the uterus. As far as any one could tell, the patient was then four months gravid. It was fair to remark that had laparotomy been performed the woman might have died, for laparotomy, no matter how carefully performed, carried risks.

He also put on record a case in which he made the diagnosis of extra uterine pregnancy, a tumor being present, and other signs of pregnancy which could not have been in the uterus, since he curetted this organ. He used electricity, and afterward a hæmatoma formed which he evacuated by vaginal puncture; again, a pelvic hæmatocele formed, and here again he inserted his finger by way of the vagina and cleaned the cavity of clots. Laparotomy could not be performed for want of assistance. The patient made a complete recovery.

Glass Pessary Worn Twenty-five Years.—Dr. R. A. Murray presented a glass ball, hollow within, which a woman aged seventy-eight, had carried in her vagina about twenty-five years. He had considerable difficulty in removing it from its embedded position.

Three Cases of Fibroids.—Dr. Murray also showed three small submucous fibroids from three different cases. All the patients had suffered much from hemorrhage, and had been treated by different physicians, who. it seemed, had not recognized the real cause of the trouble, but attributed it to the approaching menopause. The cases illustrated the necessity for examining all women who bled about the time of the climacteric.

The Treatment of Incomplete Abortion at Roosevelt Hospital.—Dr. H. G. Locke read a paper with this title. In the class of cases treated at the hospital there was seldom any hope of checking the abortion, in many there had been exposure to sepsis, in many the condition was due to criminal practice. They could not therefore have much surety of the patient's safety without placing the uterus beyond the possibility of infection. The expectant plan of treatment was hardly practical. They proceeded as soon as possible to empty the uterus. If hemorrhage was not too great, the patient was given a good bath. The operation was done with all the precautions that were taken in laparotomy. The external genitals were thoroughly scrubbed and washed with bichloride, the patient put in the lithotomy position, the vagina, fornix, and cervix scrubbed with soap and water and disinfected with bichloride, the cervix cleansed of mucus and washed. Then, with an assistant holding the perineum back with a speculum, another holding down the cervix with a tenaculum, the uterus grasped and held through the abdominal walls, the surgeon proceeded, if the cervix were not sufficiently dilated, to dilate with the metal dilator. Then the uterus was emptied of ovum and membranes and shreds by the finger, the lion jawed forceps, and curette. It was then irrigated with bichloride, and if contraction did not take place and stop hemorrhage, tincture of iodine was applied, and in later cases they might introduce a tamponade of iodoform gauze, which was gradually removed during the twenty-four hours, commencing after the third hour. The bladder was emptied by catheter for twenty four hours. The patient usually remained a week.

The Method too Complex.—Dr. R. A. Murray thought the method outlined rather complex to be useful in private practice, and in hospitals simpler methods should be used in order that physicians training there might be able to apply them outside where few assistants could be obtained. He believed there was no necessity, short of hemorrhage or sepsis, for interfering with the uterus. Cleanse the vagina, for until this was done we could not say that an odor was from the uterus and not from retained clots in the vagina. If now the tip of the finger introduced into the cervix had a foul odor, the uterus should be entered. He would not use any puncturing intrument in holding the cervix, lest it might thus be inoculated with septic matter. The metal dilator caused pain, and therefore an anæsthetic should be given; unless the uterus were held, it was liable to slip and do harm. He thought dilatation could be effected with tampon or tent with antiseptic precautions. After the uterus had been emptied completely, all hemorrhage, according to his experience in cases up to the fourth month, would stop. He had never introduced the tamponade into the uterus, even at full term; in abortion, as in normal labor. he applied the antiseptic pad.

Dr. J. Clifton Edgar thought that where the abortion was not complete—at, for instance, the third month—forcible dilatation would result in retention of some of the membranes and necessitate curetting, whereas if the plan were adopted suggested by Dr. Murray, the vagina rendered aseptic, and a tampon introduced, the ovum would probably come away without rupture, rendering subsequent curetting unnecessary. Where it was necessary to empty the uterus immediately, sometimes the ovum could be grasped with the forceps and be removed with the membranes complete, obviating the necessity for curetting or introducing the finger. He would feel that the bullet forceps were safer than a tenaculum.

The Chairman thought that under the limitations stated in the paper, of incomplete abortion, the method described was an ideal one for a hospital, but it was not applicable in private practice except in the better walks of life. It was not always possible to have a nurse, someone to hold the speculum, another to hold the bulldog forceps or tenaculum, and, so far as his experience extended, it was not necessary. He had seen many cases of abortion, and had lost none. As a rule he had had to do all himself—to give the anæsthetic, dilate the cervix, clean out the uterus. He used hot water, but no germicides; he had found no need for the gauze tamponage before the fourth month, and if he should ever employ it he would leave the iodoform out. If the uterus were septic he would use the sharp curette and then throw in peroxide of hydrogen.

The Utility of a Thorough Examination.—The *Hospital Gazette* tells the following tale of the rapid rise of a medical man in London into fashionable business, on the authority of a fellow-practitioner, and possibly an envious rival. He was conversing with a lady's maid in an aristocratic family, one of whose junior members he had been attending, and he ventured to ask "How is it that the Duchess thinks so much of Dr. Goosely Robinson; usen't she to be a homœopath?" "Oh, yes, sir, she was, but this new doctor just suits her Grace; he's very pleasant in his manner, and even when there's nothing the matter with her he examines her so very carefully—in fact, you know, *stereoscopes* her all over."

Three Deaths from Chloroform have recently occurred in London: One in a man, aged twenty-seven, about to be operated upon for cellulitis of the leg; another in a man, also young, with varicocele; and the third in a young girl with an abscess of no great size—all three cases in which without the chloroform the young people would doubtless be alive to-day. It does take people a long time to learn that ether, dangerous as it may be, is a safer anæsthetic than chloroform.

Correspondence.

THE HEALTH RESORTS ON THE RIVIERA.

I.—Costebelle, Hyères.

(From our Special Commissioner.)

To the Editor of the Medical Record.

Sir: Here I am writing my first Riviera letter, seated at an inoffensive little table in a plainly furnished room, which in a few weeks from now will have been completely transformed by the magic wand of Reigning Sovereignty.

Where England's Queen will Live.—For it is destined to be one of the suite of rooms that for years afterward will be visited by reverent crowds of admiring Anglo-Americans, because Britain's Queen will then have used it as her most private parlor (in English, "drawing-room"). It is, of course, eminently proper that through the columns of the Medical Record the world at large should for the first time learn something definite and reliable, especially about sanitary matters, in connection with the Queen of England's spring resi dence on the Riviera.

Having spent the past few days at Hyères, or more correctly speaking, at Costebelle, I have no hesitation in saying that the august lady must have had very competent advisers. For this quaint old town is certainly one of the most lovely, as it is well known to be the most southern, of all the numerous "winter stations" along the north shore of the Mediterranean.

The Hermitage and Costebelle Hotels.—As a general thing I am quite willing to take my chances for getting pretty near the truth by the easy method of saying just about the opposite of what the familiar shyness and modesty of continental hotel keepers forces them to reluctantly admit concerning the surpassing excellences of their properties. But in the case of the Costebelle hotels I must really make a departure from my usual method, for M. Peyron, the French proprietor of the place, has told only the truth when he claims that the Costebelle or Ermitage winter station is one of the loveliest and least known of all the health resorts on the Riviera.

From the railway station of Hyères it is but one mile of slightly up hill wooded road to Costebelle. From the town proper it is two miles in a southerly direction. From Marseilles to Genoa, *i.e.*, along the entire Western Riviera, or "*le littoral*," as the French call it, there are ever-changing and enchanting views. But in all this favored strip of land, so abundantly blessed with blue skies and health-giving sunshine, I have found no prettier views than those which are enjoyed from the Costebelle hill-sides.

Situated on the southern slope of an eminence appropriately named, "Mont des Oiseaux," which effectually protects it from that much-dreaded wind called "mistral," surrounded by forests of aged pines, oaks, and olive trees, that richly clothe in different shades of green the adjoining hills on the north, east, and west, and with a southerly view over undulating woodlands, stretching out into a picturesque plain that ends abruptly at the Mediterranean Sea a mile below, Costebelle has been happily chosen as a site for a few first-class hotels. Even now they are all too small for the crowds already flocking to the spot where British royalty will soon hold sway.

Why Costebelle and Hyères are so Little Known.—Quite apart from the transient interest that Costebelle will excite on account of the Queen's visit, the place has intrinsic merits that entitle it to be far better known in America than it has been in the past; and this remark applies to Hyères as well. The reason why Costebelle was so little known is thus explained. Costebelle is the newest, as Hyères, of which it is the suburb, is the oldest of the Riviera winter resorts.

When Cannes, by a mere chance, was preferred by the late Lord Brougham to Hyères as a winter residence, it suffered but a slight injury compared to that which the Paris, Lyon & Méditerranée Railway dealt it when they decided to run their line directly to Cannes, leaving Hyères to be served some years afterward by a branch line. How the town authorities could have quietly submitted to be thus isolated they themselves do not now understand.

For some time, however, constant agitation has been made on the subject, and, at last, promises have been made by the Railway Company to materially improve the train service of Hyères, and to render more apparent to visitors the advantage it has of being three hours nearer to London than the next station, *i.e.*, Cannes. Another reason for Costebelle not being more generally known is the short time it has been in existence.

The late Duke of Grafton some years ago found it to be a site without parallel along the whole coast. He built a princely villa and made a road through the pines to serve it. But only within the last ten years has any move been made to provide accommodations for the increasing number of visitors.

In addition to the two hotels selected for the Queen, Costebelle has a third and quite modern hotel, called the Albion, which is in every respect a first class family residence.

Famous Costebelle Villas.—Separated from these buildings by beautifully shaded foot-paths is the residence of Ambroise Thomas, the celebrated composer of "Mignon," then that of the Count de Leautaud. From thence her Majesty, and even lesser mortals, will be able to pass into the gardens of the Château de Saint Pierre, an odd-looking structure, erected by M. Germain de Saint Pierre, the tutor of the last of the kings of France. Beyond is the villa of the Duchess of Grafton, built by the late Duke, who is erroneously credited with being the first to have discovered the advantages of Costebelle as a winter resort. The Grafton villa is at present occupied by the Duchesse de Noailles The Queen will therefore have a very extensive park at her disposal, and as it is traversed by no main roads it will afford all the quietude and privacy which she seeks during her continental sojourn. American fanciers of real blue blood—and, as is well known, we do raise that variety of fish in our muddy republican waters—Americans of this stripe, I say, should lose no time to secure accommodations now.

I will wind up this letter by a brief account of the sanitary arrangements at Costebelle, and the climatic advantages of Hyères itself, so undeservedly unknown in the United States.

The Water Supply of Costebelle.—This is the same as that of Hyères proper. The water itself is of a very hard variety, and deposits calcareous particles in abundance. It is conducted in iron pipes from a reservoir to the houses and hotels.

The Trou des Fées.—On the top of a hill (345 feet) opposite the east side of the Oiseaux peak, is a cave called the Trou des Fées. The entrance is by a vertical cavity, resembling a well. The interior, covered with stalactites, is about ninety six feet long by forty feet wide. To explore it lights are necessary. The hole is not very easy to find, though a path leads directly to it. It is situated under some fir trees. The road down by the eastern valley of the Montagnes des Oiseaux to the Costebelle road passes near one of the principal springs which supply the town. The other source is in the plain, on the road "du Père-Eternel," nearly two miles southeast from the town. It is pumped up by an engine of twenty-six horse-power. The water filters to this place from the Gapeau, one mile east, through the gravelly soil of the plain There are thus fairly good safeguards against contamination by organic impurities. An analysis of the water I was unable to obtain, but, of course, it is not every alimentary canal that lime-water is suited to. Patients will do well to seek medical advice before freely drinking it.

Drainage and Sewage Disposal.—The town of Hyères is run on the cesspool system, as are the hotels of Costebelle. In the latter I found modern trapped and reinflushed basins, with a two gallon cistern tank and pulley to each closet. But there are no separate vent-pipes for every basin. There is, however, one large trap, properly ventilated to the roof outside the hotel. Into this empty the house-pipes. The sewage then runs down hill into an ample and well-cemented cesspool, some two hundred and fifty feet distant from, and much below the level of the hotel. Unfortunately they allow the kitchen waste-pipe to empty into the main sewage pipe nearer the cesspool than the trap. Hence it is quite possible for foul gas to get into the kitchen from the cesspool But as the proof of the pudding is in the eating, I must state that there was no odor in the kitchen except the proper and becoming *mêlange* of little smells that Gallic (not garlic) culinary departments always fondly harbor. Still, the system of running kitchen waste-pipes into the general sewer is not a commendable one, and will probably be altered before the royal advent.

The Climatic Advantages of Hyères. — Hyères proper, as already intimated, is undeservedly unpopular, or unknown. True, some English families continue to go there, but Americans give it the cold shoulder, and why they do so the American only knows, and he won't tell. The proximity to vice and the gambling-tables of Monte Carlo undoubtedly have something to do with the case. But the very absence of grosser amusements should recommend Hyères to a refined minority of chaste pleasure-seekers, as well as to actual invalids in search of a quiet natural sanitarium.

Through the courtesy of Dr. Biden, for many years resident at Hyères, I am able to present to the readers of the MEDICAL RECORD observations not hitherto published in any Riviera guide-book.

Synopsis o Meteorological Observations Taken at Hyères.—The shade thermometers are placed in a Stevenson's screen. The screen stands in the open, completely exposed all around, quite away from buildings and walls. If $\frac{1}{100}$ of an inch of rain is measured in the twenty-four hours it is considered a day on which rain has fallen.

Month.	Mean shade temperature. Thermometers registering and correcting.		Mean daily shade temperature.	Solar radiation (black bulb in vacuo).	Relative humidity, daily mean.	Days of sunshine per month.	Days of wind.				Rainfall.
							Days calm.	Light to fresh.	Strong to a gale.	Days on which rain has fallen.

Indications and Contra-indications.—"The winter climate of Hyères and Costebelle is suitable especially for consumption, chronic bronchitis, asthma, heart disease, and rheumatism, also Bright's disease, gout, incipient paralysis, and the feeble constitution of delicate children. In consumption, obviously, the disease is most amenable in its early stages. Nevertheless, remarkable instances have occurred of relief in advanced cases of a type quite unsuitable to Alpine climates. The occurrence of hemorrhage is not a contra-indication to residence here. For those beyond middle life it is difficult to conceive a more suitable environment than Costebelle offers. The climate of Hyères is less exciting than that of Cannes and Nice" (Dr. Sawtell). "The chief attractions of Hyères are its climate and the beauty of its environs, which render it an agreeable place of winter abode, even for persons in health, who do not require the animated movement and recreative resources presented by large towns, and who are in tolerable walking condition. The walks and rides, both on the plain and through the cork-tree woods, by which the hills are for the most part covered, present considerable variety, while from the more elevated positions charming prospects may be enjoyed" (Dr. Edwin Lee). The barometer is high and steady. But on the Riviera, as elsewhere, every winter varies in the rainfall and in the degree of cold; and, therefore, it may happen that the traveller's experience will not agree with the stereotyped meteorological tables.

Drs. Biden and Cormack, the only English physicians residing at Hyères (with customary accuracy the 1891 editions of Riviera guide-books give the names of doctors long since deceased), agree in assuring me that Hyères is a healthy town. There is very little typhoid, no diphtheria or other zymotic diseases, and the foreign colony has nothing to fear, and nothing to regret at this delightful winter resort. Anæmia and American neurasthenia should do particularly well there. About the only contra-indication for a winter's residence at Hyères is furnished by recent neuroses, with a tendency to mania.

Accessibility of Hyères.—Hyères is about eighteen hours from Paris. From London you can reach it by the "train de luxe" in twenty-five and one-half hours. In addition to the old route there is now a new line of railway, entirely independent of the Paris, Lyon, Méditeranée. It has been opened during the past two years from St. Raphaël to Hyères. "This line belongs to the Chemin de Fer du Sud de la France, and runs along the coast of the Mediterranean, through the most beautiful and picturesque scenery of the Riviera.

"American visitors to the Riviera would be well repaid by breaking their journey at Hyères, or rather at Costebelle (which is a suburb of Hyères) for a few days, so as to enjoy the natural beauties of this spot, and then proceed to Cannes or Nice by the above route. The time occupied by this railway is precisely the same as that of the Paris, Lyon, Méditeranée. The advantage is, that you pass through a lovely country, studded with quaint old towns perched on the tops of hills, with the remains of old feudal castles towering over the other houses, instead of being dragged along for three hours through an uninteresting plain, with nothing but olive-trees on either side."

HYÈRES, December 28, 1891.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DISCUSSION ON INFLUENZA AT THE MEDICAL SOCIETY OF LONDON — EIGHTY SIX NEEDLES EXTRACTED FROM THE BODY OF AN EPILEPTIC PATIENT—RAPID HEART—XANTHOMA DIABETICORUM—THE RECENT ELECTION AT ST. THOMAS' HOSPITAL—DEATH OF SIR J. RISDON BENNETT.

LONDON, December 29, 1891.

THE adjourned discussion on influenza was resumed at the last meeting of the Medical Society. Dr. Symes Thompson said he thought there was evidence that nervous disturbance was not merely an accidental sequel of influenza. Any shock to the nervous system might check brain trouble, and that might explain the fact related by Dr. Savage, that acute insanity was sometimes removed by an attack of influenza. He had seen some curious evidence of neuroses, such as herpes, in the course of the fifth nerve. Alluding to the theory that lung affections were due to the removal of nerve control, he said there was a good deal of evidence of serious affection of the function of the vagus, such as sharp attacks of dyspnœa with marked pulmonary manifestations. In several cases he had met with tachycardia, the heart-beats reaching 200 a minute. Recumbency was desirable, if only on account of the heart weakness. When heart failure did occur, it

seemed to be due less to sheer nerve weakness or valvular defect than to a violent disturbance of the nervous system controlling the heart's action.

Dr. Sansom said he had not seen much acute delirium or insomnia, but had met with some of the more usual complications, some of which puzzled him extremely. One patient was suddenly seized with intense liver pain, simulating colic, lasting an hour. He had also met with cases simulating angina pectoris, and even when not associated with pain there was often marked cardiac perturbation. In other cases there were nervous disturbances akin to those met with in alcoholic neuritis. He concluded that the influence of the poison could not have been exerted generally on the nerve-centres, for the symptoms were too localized.

Dr. Bezly Thorne said the real danger of influenza began where most people supposed it to end, viz., when convalescence commenced. He thought every case of influenza should be treated as one of cerebro-spinal concussion, and kept in the recumbent position.

Dr. Sisley asked whether Dr. Savage thought insanity protected against influenza. He had observed that prisoners escaped largely during the great epidemic, and it occurred to him that this must be due to their isolation; the same thing would obtain in lunatic asylums. The statistics as to the supposed protection of soldiers in Germany were by no means convincing.

Dr. Heron thought the spread of the disease might be checked by isolation.

Dr. Guthrie pointed out that the poison was both irritant and depressant, and the irritant sometimes predominated. He insisted on the functional nature of the neuroses of influenza.

Dr. Paramore drew attention to hyperpyrexia as a cause of death.

Dr. Althaus then replied, and said that though the local nerve disturbance was often very marked, there was indisputable evidence of derangement of the general nervous system. Revaccination was less methodically carried out in the French than in the German army, and the virulence of influenza was far greater in the former than in the latter, but he admitted that such comparisons were misleading.

Dr. Savage, in reply, said that in several cases of melancholia finding the pulse at 110 or 120 had led him to inquire whether there had been an attack of influenza, and he invariably found such had been the case. It was curious how the inmates of lunatic asylums suffered in smaller proportion than the attendants; in one asylum half the attendants were attacked, but only ten per cent. of the patients. The average physician would lose sight of his patient when convalescence set in, and that was just when the mental symptoms came on. He had no doubt that influenza was a potent factor in the production of general paralysis of the insane in certain subjects.

At the last meeting of the Clinical Society Dr. Bastian read notes of the case of an epileptic woman, an inmate of the workhouse at Guisborough, from whom eighty-six needles had been extracted at intervals from various parts of the body. Seven of the needles were very large —from three and one-quarter to three and one-half inches in length. Fourteen others were still to be felt in various parts of the body. The patient was now fifty five years of age and had been subject to fits from early childhood; she sometimes had several in one day, and rarely passed a day without having one. Needles were first noticed in her body after she had been in the workhouse about twelve months, during which time she had been accustomed to do much sewing and often had packets of needles in her possession. The needles had all been extracted by the doctor, the nurse, or the matron, or by the patient in the presence of one of them. With one exception, they had all been extracted from some part of the left side of the body.

Dr. Buckland read a paper on a case of rapid heart in a girl of eleven. Several attacks occurred, one in the course of an attack of measles. There was no evidence of structural cardiac change, and he regarded the case as a neurotic one. Treatment by means of stimulants, heart tonics, blisters to the neck, and the application of the constant current to the region of the pneumogastric in the neck was not followed by any benefit.

At the Pathological Society Mr. Malcolm Morris and Mr. J. J. Clarke showed a case of xanthoma diabeticorum —the eleventh on record. Mr. Clarke described the microscopic characters of the lesions as seen on examination of a small piece of skin which had been excised. The authors reviewed the literature of the subject, and concluded that the disease was essentially the same as ordinary xanthoma. They thought its anatomical characters might be summed up by describing it as a chronic deep dermatitis with early fatty degeneration.

The surgical staff at St. Thomas's Hospital has just been increased by the election of a fourth assistant surgeon. The circumstances attending the election have occasioned no little discussion during the last few weeks. A vacancy for an assistant surgeon having occurred, there were two candidates who were considered as having strong claims, having both of them done important work for the hospital while holding various appointments. One of them, however, was some years senior to the other, and had also (what has hitherto been regarded as an essential before being elected on the staff) held the appointment of resident assistant surgeon, which his younger rival had not. The latter, nevertheless, was recommended for election by the members of the staff. The Grand Committee of the hospital refused, however, to confirm this recommendation. After considerable discussion, and a further consideration of the subject by the committees in question, the difficulty has been got over by electing a fourth assistant surgeon as well as filling the vacancy. This appointment has been bestowed on the junior candidate, Mr. Ballance, the other vacancy being filled by the election of Mr. Battle.

The death is announced, at the age of eighty-two, of Sir J. Risdon Bennett, a past president of the Royal College of Physicians.

FAVORITISM AT THE NEW YORK ACADEMY OF MEDICINE.

To the Editor of the Medical Record.

Sir: "The object of the Academy shall be: The Promotion of the Science and Art of Medicine, including the maintenance of a Public Medical Library."

The above is Article II. of the Constitution of the New York Academy of Medicine, and the object of this communication is to state my reasons for believing that the provisions of this Article are at present carried out in a narrow, exclusive, and partisan way. I will be as concise and brief as possible.

For some time it has been the custom of officers of the Academy, either spontaneously or at the request or instigation of others (possibly the readers of papers), to append, on the card of announcement, a list (of variable length) of those who will open and carry on the discussion of the paper of the evening when read. This list may contain anywhere from one to twelve or more names, and we claim that this assumption of authority by those in power is in direct violation of the above-mentioned "object" of the Academy, and diametrically opposed to the best interests of the organization.

Let us study its working in a sample meeting. At eight o'clock, if a quorum be present, the following order of business is commenced and pursued: The minutes are read; the Council, Trustees, and Committee on Admission report; new Fellows are admitted; the Corresponding and Statistical Secretaries and the Committee on Library report; Sections report in their order; then come reports by leave; then the paper of the evening is an-

nounced. By this time it is never earlier than 8.30 P.M., and oftener much nearer 9. The paper over and the favored few debaters having parted with some of their residual air, the hour of 10.30 P.M. is generally reached, discussion is closed, and a motion to adjourn is made and carried. The bewildered new member, after a few experiences like this, queries in what respect he is any better off than an outsider. Any outsider can consult books in the library but cannot take one home; no more can a member. Any outsider can attend meetings and hear papers read, but cannot discuss them; neither can ninety per cent. of the members. If of a speculative turn of mind the member might then well say, "What object is there in belonging to and helping to support an institution so partisan and undemocratic?" Did someone answer, "Honor?" There was a time when it was some distinction to belong to the Academy, but I claim that time is past. Need of money and the demand for plastic material for caucusses have thrown wide open the doors, with the result of making the Academy, professedly a popular medical body, unselfish and democratic in the matter of receiving large dues, selfish and undemocratic in returning anything approaching a fair equivalent therefor.

The Academy is a deliberative body, and as such should follow rules governing other deliberative bodies. A slight recognition of this duty appears in Section 10, By-Law 23, of the Academy, which says, "All questions of order, not provided for by these rules, shall be determined by parliamentary usage as expounded by 'Cushing's Manual.'" My claim is that no deliberative body extant has the right to mould debate or gag discussion. The dictates of ordinary parliamentary law are plain. The paper read, it should, by the presiding officer, be presented for discussion. The first member on his feet, properly addressing the chairman, should be accorded the floor and allowed an allotted time, provided his remarks are relevant and decorous.

The abuses possible in any other conduct of debate are numerous. Suppose the reader of a paper containing some startling innovation or radical or revolutionary ideas should designate as proper persons to participate in debate only those pledged to or favoring his ideas. In this way any criticism or condemnation, however much deserved, might be suppressed, and the meeting might resolve itself, as it often does, into a mutual admiration society. Healthy criticism, honest contention, and the free and full expression of adverse views do more to "promote the science and art of medicine" than any amount of unquestioning acceptance of radical views or servile adulation of imaginary superiority.

Again, it is preposterous to assume that any man, or clique of men, can justly select a few members as pre-eminently fit to discuss a certain question to the entire exclusion of all others. Age can be no criterion, as all will agree. Experience, while a better guide, is a qualification the only judge of which is the individual member himself. The bringing into prominence and advancement of one's favorites, irrespective of their abilities or acceptability to those who must listen to them, should be beneath men pledged to help "promote the science and art of medicine." But is it not done? I will leave it to unprejudiced readers if, in a popular and democratic body such as the Academy has become, free and untrammelled debate is not the only just procedure. Whence does the Academy expect to derive its talent in years to come if it continues to exclusively parade its war-horses of debate who have for decades stamped and pawed the floor and tossed about themselves the stifling dust of supremacy.

It must be that among the numerous recently acquired members there are some talented debaters, some men of original ideas, some men with practices and experience far surpassing their reputation.

No one can doubt that such men exist, and common justice should revolt at their neglect and demand the recognition of their rights.

Advocates of the present mode of conducting debate urge as an excuse that unless certain men are especially invited and publicly announced to participate in discussion they will not attend the meeting. To this I would say that if men are not sufficiently interested in the subject under discussion to attend without being cajoled or bribed by public announcement of their assumed superiority, then they had better stay at home.

Again, advocates of cut-and-dried discussion will say that unless debaters are assigned, announced, and called upon, men fond of hearing themselves talk and saying little that is pertinent or instructive will monopolize the floor. If this should result, it would be the fault of the presiding officer and the audience, as it is a duty of the former to stop rambling and irrelevant discussion, and the privilege of the latter to express in many ways their dissatisfaction at mere verbal hypercatharsis.

Another abuse to which the Academy, as well as, I am sorry to say, some other medical organizations is addicted is the aping of sharp political tactics in the conduct of its primaries or meetings for the nomination of officers. By sharp practice the ruling clique prevent the nomination of but one candidate for any office for which they care, thus rendering his election certain. Mind, I don't question the legal right of such action, but I do claim that such practices should be beneath the dignity of physicians.

Men cannot be so foolish as to imagine that where only one nomination is allowed the resulting unavoidable election is unanimous, but they hunger and fight for it just the same, and, having gained, seem satisfied with it. Of much greater honor would be an official position attained after a little healthy competition and friendly rivalry. That other, perhaps greater grievances exist in this august body I don't doubt; but in my unofficial connection with the Academy they have escaped my notice. That abuses calling for protest and rebuke do exist is known to all; but as there seems to be no disinclination, on the part of the rank and file of the Academy to be led by the nose by their self-constituted rulers, there would seem to be little call for this communication except as an individual protest against the prostitution of a public trust to the furtherance of personal ends and the advancement of favorites and cliques.

R. W. AMIDON, M.D.

19 WEST TWENTY-FIRST STREET, January 11, 1892.

MECHANICAL CONTROL OF THE CIRCULATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The excellent practical suggestions of Professor R. H. M. Dawbarn on this subject may possibly call attention to the much-neglected, though, I think, most important, contribution of the present century to practical therapeutics, which I have urged upon my students ever since 1847.

Professor Dawbarn thinks his suggestion an old one, long neglected and "lapsed," but, in fact, it is a small portion of an extensive system of mechanical therapeutics, developed by M. Junod, of Paris, who began his labors in 1833. Dr. Junod was not only highly commended by the Academy of Sciences, but twice received the Monthyon prize. His last grand medical and surgical prize was given in 1870, and a prize of 1,500 francs as late as 1876. A few years later than Dr. Junod, Dr. F. H. Buckler, of Baltimore, struck upon the same principle and published some very striking illustrations of the power of hæmostasis to control the circulation, to overcome pneumonia, and to produce a far greater impression on the circulation than could be produced by bleeding, without any of its deleterious effects.

His experiments were very interesting and convincing. I would mention only one illustration. C. P——, a negro chambermaid, aged twenty-three, robust and tall, and always in good health previously, attended a party, and coming from the hot, crowded room through a cold,

damp atmosphere, without sufficient clothing, she was taken with an icy coldness of the whole body. through the most of the succeeding day, followed at night by "aching and soreness in all her limbs, violent pain in the back, and severe headache." Next day Dr. Buckler saw her, suffering with violent headache, soreness of limbs, great weakness, and slight cough, but no expectoration. His treatment was by blood-letting and antimony, taking on the first day fifteen ounces, on the second twelve ounces, on the third ten ounces, with a little calomel and ipecac. The symptoms of pneumonia progressively developed and went right on toward a fatal result, without the slightest benefit from his treatment. She had no sleep from the beginning; her tongue was white and dry; pulse, 120, and corded; countenance exceedingly anxious, blood with inflammatory buff, bronchophony and bronchial respiration marked, dulness over lower half of left lung behind, and fine crepitation in other parts of it; a coarse bronchus was heard, and the vesicular murmur absent in lower half of left lung.

The patient being unable to sit up, and death apparently impending, the ligatures were then applied on the upper part of each thigh. As soon as they were fastened she complained of weakness and sick stomach. The pulse became softer and less frequent, and the skin relaxed. She complained of numbness in the legs in an hour after the ligatures had been applied, and the limbs were much gorged. The medicine was stopped and the case left to the ligatures alone. They were kept on twelve hours, and during that time she got three hours' sleep, the first sleep since her attack. The pulse was 100, and soft, the skin soft and natural, tongue moist, countenance cheerful and bright, and she said she felt much better. The lung gave better symptoms to auscultation.

The ligatures were renewed, to be kept on until painful. Next day she was better, coughed and expectorated freely. The treatment by ligature was kept up, being once kept on fourteen hours at a time. They kept down the pulse and kept the skin in good condition. She steadily improved without medicine, using only barley-water, and was well on the seventh day after medicine had been dropped to rely on ligatures alone.

This is a synopsis of Dr. Buckler's report of his first application of hæmostasis to pneumonia. His previous experiments on patients were very decisive, showing that in some cases ligatures alone might exhaust the central circulation to the extent of producing fainting.

It is not merely by impairing the force of the circulation that ligatures are successful in controlling hemorrhages and inflammations, but by positively withholding a large amount of blood from the inflamed organs, more than could be produced by the boldest bleeding. When combined with small bleedings the effects were very striking. He showed that a twenty-four ounce bleeding without ligatures is far inferior in effect to a four-ounce bleeding when the patient is subjected to ligatures.

The loss of the mechanical control of the circulation by laying aside the lancet is a serious loss in some few cases, and why the profession has neglected to use this far more powerful agent, which has a really decisive control over hemorrhage and inflammation, cannot be told without impeaching professional wisdom.

But this Buckler method of hæmostasis, powerful as it is when applied on all four limbs, at the shoulders and thighs, is a crude and unsatisfactory method compared to the pneumatic control of the circulation called hæmospasia, which was so triumphantly displayed by Junod for many years, and received the sanction of the highest medical authorities of France, many of whose names are unfamiliar to English readers, but I might mention many names among the supporters of Junod's method which are familiar to all students of medical literature, such as Andral, Bouillaud, Velpeau, Nélaton, Rostan, Ricord, Malgaigne, Louis, Dubois, Baudelocque, Cruveilhier, Trousseau, Piorry, Cazenave, Boyer, Voisin, Rayer, Fouquier, etc.

The methods of Junod were applied successfully by himself and his pupils, not only in inflammations and hemorrhages but to a host of diseases of the respiratory and digestive organs, affections of the heart, head, and nervous system, uterine and urinary diseases, fevers, cholera, rheumatism, gout, and many surgical cases, in all of which its value was demonstrated either as an adjunct to other measures or as the main reliance.

To illustrate his methods, their sound philosophy and practical success, would require quite an essay, but if desired I would take pleasure in giving an exposition of what I deem the greatest contribution of the century to practical therapeutics, and in showing that its application is not forbidden either by the extensiveness or the complexity and difficulties of the apparatus, as many have supposed.

I cannot account for the neglect of Junod's pneumatic methods, except by the aversion of the profession to adapting mechanical methods which are more laborious than writing prescriptions. Over twenty years ago, in consultation with two gentlemen, one the foremost physician of his city, and the other an ex-president of the National Medical Association (in a case of pneumonia) I found that neither of them had ever heard of hæmospasia. Yet attention has recently been given to other pneumatic methods, such, for example, as increased atmospheric pressure, the results of which are but trivial in comparison with the great range of utility developed by Junod and Buckler, and endorsed by the highest authority.

J. R. BUCHANAN, M.D.

KANSAS CITY, January 5, 1892.

INCREASED DUES OF THE ACADEMY OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Doubtless many Fellows of the Academy, who were not present at the meeting of December 3d, were surprised to learn from the MEDICAL RECORD that their dues had been doubled. The writer most certainly was, and he thought there must be an error in the report until the mail shortly after brought a bill from the Treasurer for $20. This is the first official intimation that the Fellows of the Academy have received of an increase in the dues, and it looks very much as though the notice had been intentionally withheld until it was too late to avoid payment for the current year. The members should have been notified in December, immediately after the passage of the amendment, so that those who felt that they could not afford to pay the extra tax could have had an opportunity to resign. It is not the increase against which I desire to protest, for the Academy has a right to make the dues as high as it pleases, and it was doubtless necessary to raise them; but the withholding of any information concerning it from the members seems to me to savor of a "sharp trick" that does not reflect any honor upon the officers responsible for it.

AN IMPECUNIOUS FELLOW.

Quacks and Reciprocity.—One of the provisions of the reciprocity negotiations with the island of Jamaica is that there shall be no duties levied on patent medicines imported from this country.

A Big Baby.—Dr. Florentin Ortega reports in the *Nouvelles Archives d Obstétrique et de Gynécologie* for October, 1891, a case of a large still-born infant. It was 2 feet 3½ inches tall, 7½ inches broad across the shoulders, and weighed 23½ pounds. The mother was a primipara, twenty-three years of age. The exact duration of the pregnancy was not known.

How much Ought a Small City to Pay Its Health Officer?—Two thousand dollars a year, says Dr. Henry B. Baker, Secretary of the Michigan State Board of Health.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 9, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	3
Scarlet fever	211	34
Cerebro-spinal meningitis	1	3
Measles	156	16
Diphtheria	121	39
Small-pox	0	0
Varicella	18	0
Pertussis	0	8
Erysipelas	2	0
Mumps	0	0
Rötheln	0	0

What was the Doctor to Do?—The *Medical Times* says that a perplexing suit has been commenced in Paris. A suburban practitioner, called to attend a patient suffering from scarlet fever, advised the landlord to disinfect the house. This was done, and the landlord sued the patient to recover the cost. The latter thereupon sued the doctor for breach of professional secrecy, and it is thought he will win his case.

Pure Drinking-water on Shipboard.—*The Lancet* says that attention has lately been directed to the impurity of much of the water used on board ships at sea, and the consequent prevalence among sailors of such characteristic diseases as dysentery, typhoid fever, and cholera, and adds that there is reason to believe that the grievance is no imaginary one, and that certainly its importance cannot be over-estimated. It urges the necessity of a careful examination of the condition and contents of all water-tanks and barrels being made before a ship starts on a voyage, and goes on to say: "A supply of such purifying agents as alum and charcoal should not be omitted, since by means of these, by boiling and by distillation, faulty water, if no better be procurable, may often be made drinkable. Better still, and much more convenient in use, would be one or more ship's filters of large size. The scandal of disease arising on shipboard from a cause so easily preventable demands, at least, the adoption of these necessary preventive measures."

Coffee and Cholera.—It is some time since a Dutch physiologist announced it as his discovery that coffee is a germicide—a sure killer of the cholera bacillus in a few hours. It is now reported from North Bhangulpur, in Bengal, that the coffee remedy for cholera is being put into practice there with astonishing success.—*Western Druggist.*

A Medico-legal Congress is to be held in Rome in September, 1892. It is said that the science of medical jurisprudence is greatly neglected in Italy, except by a few well-known and justly celebrated specialists.

A Suitable Vehicle for the Administration of Medicines.—A Philadelphia physician was called by a foreign family, and prescribed one pill to be taken three times a day in any convenient vehicle. The family looked into the dictionary to get the meaning of the prescription. They got on well enough as far as the word "vehicle." To this they found "cart, wagon, carriage, wheel-barrow." After a grave consideration they came to the conclusion that the doctor meant that the patient should ride out, and while in the vehicle he should take the pill. The supposed advice was followed to the very letter, and in the course of a few weeks the fresh air taken so regularly completely cured the patient.—*Medical Times.*

The Plague in London.—Among the items of interest in a volume on the "Population and Growth of the City of London," recently issued by the London Corporation, are extracts from the bills of mortality which were first published by the Ancient Company of Parish Clerkes in 1592. From these, some idea of the awful ravages of the plague may be gathered. In 1603, 30,561 persons died of it in 147 parishes of London, Westminster, and Southwark; in 1625, 35,417 persons; and in 1665, the year of the "Great Plague," 68,596; the population of London then, as ascertained by the rough and ready method at that time adopted, being well within half a million.—*British Medical Journal.*

Novelty at the Chicago Exhibition.—The forthcoming "World's Fair" at Chicago is to be graced by a novelty which is in process of manufacture by a Pittsburg medical man. This consists of an immense papier-mâché model of the human heart. It will be three feet in diameter. We trust that precautions will be adopted to prevent the left ventricle of this model from being mistaken for a retiring-room.—*Medical Press.*

A Hardy Sceptic.—Dr. H. W. Middendorp, of Groningen, Holland, has never accepted the theory of the bacillary origin of tuberculosis. He has recently published a pamphlet entitled, "New Studies Concerning the Tubercle Bacilli which Professor R. Koch claims to have discovered, but which do not Exist; the Falsity of his Doctrine of the Etiology of Tuberculosis, and the Uselessness and Dangers of his New Mode of Treatment."

A Full Bladder.—Dr. Williams relates a remarkable case in the *Lancet* of October 31, 1891, where 205 fluid ounces of urine were withdrawn from the bladder of a man who did not know his bladder was full, although it extended to within an inch and a half of the xiphoid cartilage. This case shows that it is never safe to perform paracentesis abdominalis without first ascertaining that the bladder is not the cause of a wave of fluid on percussion.

One Breast or Two.—In a recent number of the *Lyon Medical*, Sabaitie referred to some observations he had made upon the mortality of infants nursed by women who for some reason used only one breast. He found that the death-rate is much higher in these cases than in those where both breasts were employed. In thirty-two of the former, among hospital patients, the infantile mortality was forty-eight per cent.; in the same number of the latter, under similar circumstances, the mortality was but twenty-eight per cent.—*Medical Press.*

Teetotal Tyranny.—A most extraordinary condition of things seems to prevail at the Plymouth Workhouse Infirmary, where some crazy teetotallers, dressed in a little brief authority, have ordained that patients are under no circumstances to be given spirits. The result was that last week a poor body succumbed to an attack of syncope, whose life, the medical officer opines, might have been indefinitely prolonged by the judicious exhibition of a little alcohol. We see no reason to question the validity of his surmise, and must express surprise and regret that such inhumanity should be shown in the treatment of the sick poor.—*Medical Press.*

A Hard Condition.—A London physician, who advertises in the daily papers that his medicines are powerful, not poisonous, but pleasant to the palate, lays down as a necessary condition for his women patients that they leave their corsets at home. He is said to have quite a large female clientèle nevertheless.

Menstruation and the Larynx.—Dr. von Klein says that it is possible to tell when a female singer is menstruating by the fact that her voice is lower in tone than usual.

A New Institution with a Big Name is the Kaiser-und-Kaiserin-Friedrich-Kinder-Krankenhaus, in Berlin.

THE CEREBRAL ATROPHIES OF CHILDHOOD.

WITH SPECIAL REFERENCE TO THE OPERATION OF CRANIOTOMY FOR IMBECILITY, EPILEPSY, AND PARALYSIS.

BY M. ALLEN STARR, M.D., PH.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE medical treatment of imbecility, epilepsy, and hemiplegia occurring in childhood is so hopeless, that the recent proposal to invoke the aid of surgery in these cases has excited much interest. The public, as well as the medical profession, is anxious to learn how far success may be looked for from craniotomy, and to obtain facts upon which to decide the question of operative treatment. To neurologists the subject is of immediate importance, for they must be responsible for advising or opposing this method of treatment.

It is with a view of getting at the facts necessary to come to a positive conclusion that this article is undertaken, and it will be my aim in stating the facts to maintain an impartial position. In studying the question of operating for brain-tumors in childhood, it was found to be of advantage to collect a large number of cases;[1] to review their pathology, and to determine what percentage might have been successfully treated by surgeons; and the same method has been followed in the preparation of this article.

Craniotomy, or the operation of producing an opening in the skull of some extent, with the object of relieving pressure on the brain, or in some unknown manner of stimulating its development, has been proposed and performed in a number of cases.

These cases present certain clinical features, and may easily be divided into three general groups: First, cases of hemiplegia with or without athetosis. Secondly, cases of mental defects of various grades. Thirdly, cases of sensory defect of different types. Epileptiform seizures of *petit mal* or of *grand mal* type occur frequently in patients who may be assigned to any one of these groups, and may be the particular symptom in regard to which advice is sought. The subject therefore includes the question of trephining in organic epilepsy in childhood.

I. Infantile cerebral hemiplegia has been studied so carefully of late, and so much has been written upon it, that no elaborate description of the first class of cases is needed. The symptoms are the sudden development of a unilateral paralysis after a series of convulsions attended by high fever and its attendant discomforts, and a period of unconsciousness of varying duration; then a gradual improvement in the paralysis after the active manifestations of the onset have subsided; and finally, a stationary condition, in which the face is but slightly affected in its voluntary or automatic movements; the speech is usually regained, if it had been lost; the arm is quite seriously paralyzed, the fingers being stiff and awkward, and sometimes being in constant slow involuntary motion (athetosis); the leg is held rather rigid, so that the child limps in walking, and sometimes has a club-foot. There are, of course, on the one hand light cases in which the symptoms finally amount merely to clumsiness in the fingers. There are, on the other hand, severe cases in which a double hemiplegia has occurred, both halves of the body being equally affected, and in which both arms are useless and both legs so stiff, so closely adducted, and so helpless that walking is impossible. These latter are cases in which all the symptoms date from birth, the birth palsies of Gowers. In all cases the paralyzed limbs are found to be affected in their growth and development, so that they are smaller, colder, stiffer, and weaker than the others; the reflexes are exaggerated, but the electrical reactions are not qualitatively changed, and the sensation is normal. This condition remains through life as a permanent defect, and although the division of contractured muscles or tendons, and the application of ingenious apparatus, may correct deformities and make the paralyzed parts fairly useful, and although the application of electricity to the muscles chiefly affected may increase their nutrition and thus prevent contractures which come from the unbalanced strain between the various muscles, yet any great degree of improvement is impossible. In more than one-half of these cases epileptic attacks are of frequent occurrence.

These cases are so common that it seems needless to cite illustrative examples. In the well-known monograph of Osler on the "Cerebral Palsies of Children," the most complete description of the varieties of the affection is to be found. In the history of one of my cases, operated upon by Dr. McBurney—which will be given later in this article—the ordinary course of the symptoms may be studied.

The chief clinical facts of importance in such cases are the time and character of the onset, the degree of spontaneous recovery, and the question whether the epilepsy is of so severe a type as to be dangerous.

The cases which date from birth must be divided into those in which there has been evidence of traumatism during labor, and those in which there was nothing about the delivery sufficiently unusual to awake the suspicion of trauma. In the former class it may be stated confidently that cerebral hemorrhage, usually meningeal, is the cause of the symptoms. In the latter class it is probable that an intra-uterine encephalitis, or some unknown cause, has prevented the fœtal brain from developing. I know of no positive means of differentiating these two sets of cases. The cases which have developed suddenly after birth are cases in which the ordinary causes of hemiplegia in adults have been acting, and, as Ashby has shown, must be traced either to encephalitis, hemorrhage, or embolism, or disease of the vessels. The degree of spontaneous recovery in any case can be pretty well determined by an examination at the end of the second year. It is evident that a complete cure never occurs.

The fits in organic epilepsy are more likely to be frequent and severe than in idiopathic epilepsy. I have one patient who has had as many as twenty convulsions daily for weeks at a time. These fits do not destroy life, but of course render life a burden, and almost any means for their relief is justifiable. When, however, they are infrequent they may be benefited to some degree by the use of bromides.

II. The second class of cases presents mental defects rather than physical symptoms. The child may be slow in learning to talk, may seem unable to fix its attention upon anything continuously, may be exceedingly active,

[1] Tumors of the Brain in Childhood, with Special Reference to Surgical Treatment. Medical News, January 12, 1889.

in constant motion—the activity being, however, aimless; may throw things about, or tear things up, or put everything into its mouth; may be very difficult to manage because of its inability to retain and combine impressions with sufficient power to reason upon them; and may therefore be incapable of appreciating the meaning of punishment, if this be inflicted. Such children may have good powers of perception, may recognize persons and objects, show pleasure at bright colors, or music, or caresses, but fail to show evidence of thought in the sense of reasoning power, judgment, or self-control. Some patients constantly drule at the mouth, cannot be taught cleanly habits, and are manifestly imbecile. Other patients are quite bright in many directions, may even be precocious, show talents in music, or drawing, or fondness for mathematics, designing, languages; yet are apparently unable to appreciate moral ideas, cannot be taught to tell the truth, are cruel and bad, will not control any of their impulses, and so are the distress and despair of parents and teachers. It is those mental qualities which are the product of the highest evolution, which have failed to develop in this class of cases. The final result is that they have to be taken care of all their lives, either at home or by attendants, being incapable of supporting themselves or directing their conduct. Many of them have epilepsy. One or two examples may be cited.

G. M——, now twenty-one years of age, has the appearance and manner of a boy of fourteen. His head is small and narrow; forehead retreating; face small, and expression stupid. He has always been a feeble-minded boy, never able to study long or to learn anything difficult, so that he is about on the level of a boy of ten in his education; and now, as he is becoming to some extent sensible of his defects, he is very moody, quiet, and retiring. He has always been hard to manage and prone to outbursts of temper, and in the past five years this irritability is increasing. He has also peculiar attacks. In an attack he is very restless, wanders about in an aimless way, hides or destroys anything he can lay his hands upon, and becomes much excited, angry, and even abusive and violent if opposed. Such attacks last for three or four hours, during which it is necessary to watch him. After the attack is over he has no recollection of what has occurred, or of what he has done. He has many symptoms of neurasthenia, probably due in part to self-abuse. He has no paralysis or defect of sensory power. He is able to read, write, play on the violin, and sketch, but cannot be employed upon anything for any length of time, and therefore is a burden to his family.

I have three cases now under observation of children aged between three and five, who are apparently bright, and capable of hearing and seeing properly, but who show no evidence of any desire or ability to learn to talk. They make crowing sounds of no special meaning, but any distinct articulation is never made, and attempts to teach them seem unavailing. All three are restless, active children, easily attracted by interesting things, but incapable of fixing the attention long on anything. They are usually in constant motion, running about, working with the hands, and cannot be quieted long. They appear to understand perfectly what is said to them, will do various things at command, notice music and noises, yet are as mute as though perfectly deaf. They present a fair degree of intelligence, though two of them are still unable to be taught to make any sign of desire to urinate, and hence are dirty. Yet to watch these children at play at home, one would not suspect any mental weakness, and were it not for the speechlessness the parents would not have suspected any defect. None have epilepsy as yet.

A little girl of eleven was brought to me recently on account of attacks of *petit mal* which had developed within two years, and had become so frequent as to occur every hour. Two such attacks occurred in my office, each lasting twenty seconds, consisting of a sudden dilatation of the pupils, relaxation of facial expression, turning of the eyes upward, falling backward of the head, and then recovery of balance just as she was about to fall. She was completely unconscious in the attack, had no warning of its onset, and no recollection of its occurrence. Slight stimulation of the surface anywhere—pinching, throwing water in the face, seemed enough to arrest the attack, though loud sounds had no such effect. This child was well developed, and very observant and active, but had no capacity for learning or for self-control. She had been trained with care, but could not read, and acted on every impulse. She was excitable, very quick in replies, impudent and saucy, delighting in doing everything which would annoy people, and it was impossible by punishment to effect any moral improvement. This defect of intelligence was associated by a very marked defect in the development of the fore-part of her head. There appeared to have been a very early union of the coronal suture, so that a decided depression existed in the skull over its situation, and a marked difference could be seen between the size of the frontal bone and the posterior part of the skull. It looked as if a cap had been applied over the entire frontal bone which had arrested its growth, while the rest of the skull had developed properly. The arch of the palate was high. In this case I advised an operation.

III. The third class of cases is less common than the two preceding, and is likely to escape observation unless carefully investigated. The patients belonging to this class present no motor or mental defects, though they may be the subjects of epilepsy. They do have defects of sensory perception. It is probable that many cases of deaf-mutism belong to this class. Rheinhardt has described a case in which permanent deafness was due to manifest defects in the temporal convolutions of both sides. Dr. Donaldson has noticed a marked deficiency of development in the temporal and occipital convolutions of Laura Bridgman, who was both deaf and blind. The following case presents so many interesting features that I give the history in full:

The girl, who is now twelve years of age, has suffered all her life from frequent attacks of *petit mal* and occasional attacks of *grand mal*, usually preceded by an epigastric aura, never by a visual aura, and her convulsions are general, never unilateral, in character. She has had from two to six attacks of *petit mal* daily, and *grand mal* attacks once a week, though at present, after a year of treatment by bromides, she has but three or four attacks of *petit mal* every week, and has had no *grand mal* attacks for ten months. Her case, therefore, presents the features of an ordinary epilepsy.

But upon investigation it was found that she had a slight divergent squint, and a left bilateral homonymous hemianopsia, the visual fields in the eyes being much diminished, not exactly symmetrically, as the diagram (Fig. 1) shows, and the field of vision extending ten degrees beyond the fixation point in both eyes, while its periphery was slightly contracted even in the clear field. This condition had never been discovered until the child was eleven years of age, although from her infancy her mother had noticed that she habitually held her head toward the left side and looked at objects with her head turned somewhat to the left, as she does now. An examination by Dr. Webster for the purpose of correcting the squint, led to the discovery of the partial blindness. The child is quite sure that she has always seen as she does now, that she has never been able to see objects approaching her from the left side. This she supposed to be natural. This fact is of some interest, as it confirms what has been stated before, that hemianopsia may remain undetected for years, or if noticed by a patient is supposed to be a blindness in the eye whose visual field is chiefly contracted.

When a cause for this symptom was sought, it was ascertained from the mother that the child had been delivered with much difficulty, that the labor was prolonged, that the head was greatly misshapen at birth, and had a large caput succedaneum over the posterior part. When the child's head was inspected, it was found that over the right

occipital region there was a very perceptible flattening of the skull, so that the vertical parting of her hair was uniformly deflected to the right. The difference between the two sides was easily noticeable on looking down upon the head from above, or by the aid of touch. It seems reasonable to suppose that this little girl has a defective development of the right occipital lobe of the brain, and that this involves the cortex and also the subcortical tract, since Wilbrand has shown with much reason that a purely cortical lesion produces symmetrical defects in the visual field, while subcortical lesions produce asymmetrical defects. The pupils respond to light thrown upon the blind field of the retina, hence the lesion is not in the optic tract. There has never been any hemianæsthesia or hemiplegia, hence the lesion is not in the thalamus or near the internal capsule.

Peterson and Fisher have shown that cerebral atrophy in infants in the motor area is followed by an asymmetrical development of the skull, the depression in the skull lying over the atrophic part of the brain. Here there is present such a depression, or rather lack of convexity, over the occipital lobe to whose deficient development the symptom of blindness points.

When, therefore, this patient presented herself for treatment for epilepsy, it became evident that she belonged to the class of cases in which the epilepsy was due to the organic disease or defect in the brain.

It is interesting to note that a certain improvement in her condition—a marked diminution in the number of fits—has occurred under the influence of bromide; but this has also been noticed in cases of epilepsy with hemiplegia of infantile origin.

The important question to decide in this case is in regard to the possibility of any surgical interference. The history certainly points to the occurrence of great congestion of the head during delivery, and the brain injury may reasonably be ascribed to a hemorrhage upon or in the occipital lobe. Such a hemorrhage compressing the lobe would prevent its growth, would finally be absorbed, leaving probably only a connective-tissue plaque or membrane. Now, it is known that brain-growth proceeds until the age of fourteen or thereabouts, and the question arises whether removal of this plaque would allow this brain to develop. It is hardly supposed that vision would be improved, but might not the epilepsy be benefited? As in the cases of hemiplegia and of mental defect, the question becomes a pressing one, involving the future of the individual.

This case is not a unique one. Moeli has recently published (*Arch. für Psych*, xxii., 2) three cases of hemianopsia due to defective development of the occipital lobe with porencephalus or great hydrocephalus, found in adults, one at least of whom had epilepsy. In all the affection must have dated from infancy. In none of these would an operation have been feasible, in fact in all secondary degeneration had developed even into the optic tracts. Henschen records two cases of infantile hemiplegia in which hemianopsia was found ("Pathol. des Gehirns," cases 32, 33); and Freund (*Wien. Med. Woch.*, 1888, No. 32) also records two such cases. It is probable that the symptom has escaped detection in some cases of infantile hemiplegia from lack of examination.

It is evident, then, that three separable types of clinical cases of cerebral disease exist, any one of which may be accompanied by epilepsy. It is of course possible that one case may present the symptoms of all the various types, and in fact there are many patients who present both mental defects, hemiplegia and sensory defects, as in a case to be described later, on which an operation was performed. One of these varying sets of symptoms, however, is usually more prominent than others, and hence it is hardly necessary to establish a fourth type including all such anomalous cases.

When a patient belonging to one of these clinical types is presented to the neurologist and the question is asked, Can surgical treatment benefit him? it is evident that a serious problem is opened. In these cases the disease is at a standstill and does not threaten life; surgical treatment is not free from danger, and the brain is still capable of great development. Can such development be aided by an operation? In many cases the epileptic attacks are of such frequent occurrence that any risk might well be taken if they could be surely stopped.

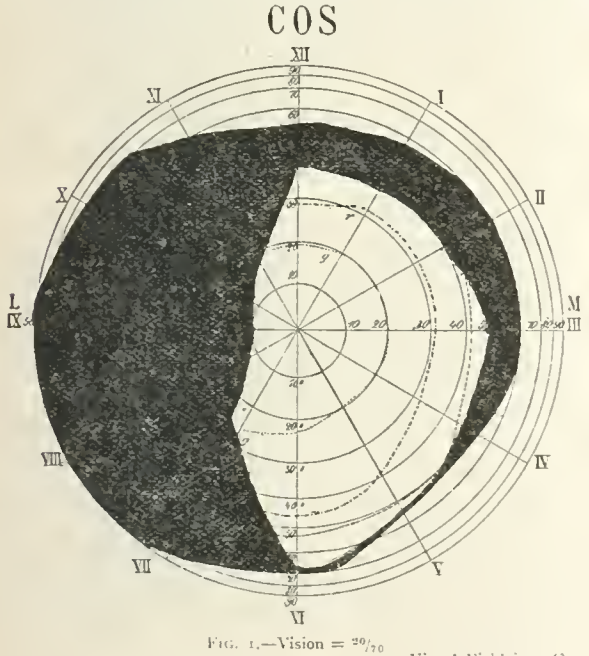

FIG. 1.—Vision = $^{20}/_{70}$

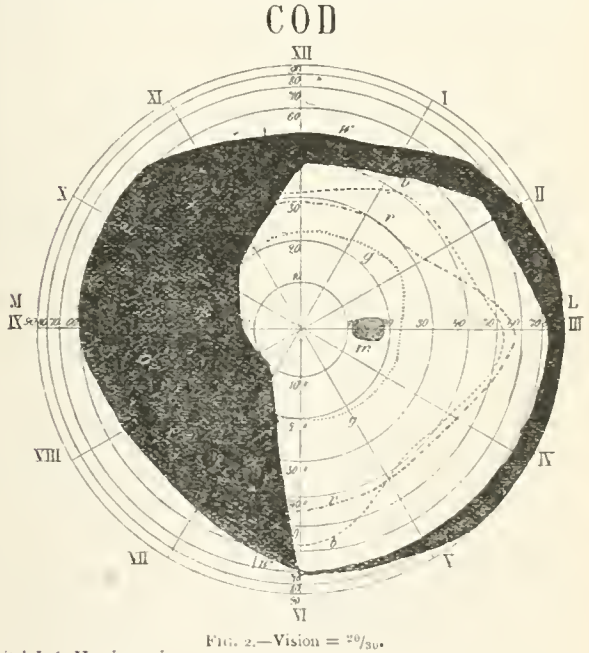

FIG. 2.—Vision = $^{20}/_{30}$.

Visual Field in a Case of Congenital Left Hemianopsia.

Any solution of the problem of operative treatment must be based upon two considerations: I. The pathology of the cases. The results of experience when such operations have been done.

I. **The Pathology of these Clinical Types.**—Records of the pathological condition found in all the three classes of cases described are now accessible, collections of cases with autopsies having been made by numerous writers.

The lesions found are various in type, in origin, and in situation, but a careful study elicits two facts: First, that the difference in the clinical types is due to the varying situation of the lesion rather than to its varying nature. Secondly, that the various processes of disease have, as a fairly uniform result, a condition of atrophy with sclerosis of the brain, which we may term sclerotic atrophy.

1. In the clinical cases of our first type the sclerotic atrophy involves the motor area of the brain, *i.e.*, the central convolutions bordering the fissure of Rolando and the cortex of their immediate vicinity, and involves also the motor tract arising from this part of the cortex, and usually the basal ganglia as well. In the clinical cases of our second type the sclerotic atrophy involves the anterior portion of the brain, and sometimes the entire hemisphere to a greater or less extent. In the clinical cases of our third type the sclerotic atrophy involves the posterior and lateral parts of the hemispheres. It is not surprising that the variation in the situation should produce varying symptoms, in view of the facts of the localization of brain-functions now known. That there should be a limitation of the sclerotic atrophy to certain lobes or regions—to the frontal, or central, or occipital or parieto-temporal regions—in various cases, has led to the hypothesis that the origin of the disease lay in some interference with the blood supply of the part, since it has often been evident that the atrophy was limited to the region nourished by blood reaching it through one arterial trunk. And this hypothesis has been supposed to explain the pathogenesis of these cases. Yet its weak point is the fact that at the autopsies the vessels usually show no evidences of disease or of plugging, and the infrequency of vascular lesions in infancy cannot be denied. Schultze is doubtless right in this matter in saying that the pathogenesis of these defects is as yet quite obscure.

2. It has been stated that the various processes of disease have, as a uniform result, a condition of sclerotic atrophy.

This fact is borne out by the following *resumé* of results in 343 cases :[1]

Porencephalus, a localized atrophy or agenesis, leaving a cavity in the cerebral hemisphere, which may be deep enough to open into the ventricle, 132 cases.

Sclerotic atrophy, an atrophic condition of the brain with an increase of connective tissue and disappearance of the nervous elements ; affecting both hemispheres, or one only, or a part of one only ; or limited to small areas in various parts, 97 cases.

Maldevelopment and apparent atrophic condition of the minute structures of the hemisphere, chiefly cortical, the cells resembling those of a new born child, but with no apparent gross defects in the brain, 32 cases.

Atrophy, consequent upon the condition of softening produced by embolism or thrombosis, and limited in extent to certain arterial districts of the brain, 23 cases.

Meningo encephalitis, a condition shown by thickening and adhesion between the pia and the brain, with destruction of the cerebral cells and atrophy of the cortex, 21 cases.

Cysts lying on the brain and producing atrophy by pressure, or associated with atrophy due to the original lesion of which the cyst remains as a trace, 14 cases.

Hemorrhage on, or in, the brain, as shown by the remains of a clot, or by hematin staining of a cyst, of the pia, or of the sclerotic tissue, 18 cases.

Hydrocephalus with extreme dilatation of the ventricles, so that the brain-tissue is reduced to a mere wall about the cavity. 5 cases.

Unilateral hydrocephalus, 1 case.

These are the conditions found at death in cases presenting the clinical features just studied. It is evident that they have this in common, namely, a condition of atrophy of the brain. The origin of this atrophy is not always clear. In some cases it is clearly congenital and due to a maldevelopment of the embryo. In other cases it is clearly traceable to injuries at birth. Again in other cases it must be ascribed to affections of various kinds, such as inflammations of the membranes, or of the brain substance, or vascular lesions and their consequences, such as occur in adults.

It is not always possible, in a given case, to determine clinically the origin of the disease. For the absence of a history of trauma at delivery does not exclude necessarily a congenital lesion. And the existence of certain symptoms in acquired cases does not always enable one to determine between an inflammatory process and a vascular lesion. Thus fever of long duration and great severity is as likely to occur in hemorrhage or embolism as in meningo-encephalitis in infants.

Nor are authorities by any means agreed as to the nature of the original pathological process of which the atrophy is the result. Wallenburg found evidences of embolism in 7 cases, and of hemorrhage in 5 cases. Osler ascribes these causes to 16 cases in his collection. Ashby describes thrombosis in 3 cases, one of them due to syphilitic endarteritis, a very rare disease in infancy. McNutt found meningeal hemorrhage in 12 cases. Gowers ascribes some of the birth palsies to thromboses of the venous sinuses. Kundrat has recently affirmed that a laceration of the veins entering the sinus is a sufficient cause for hemorrhages during delivery.

Henoch, Oliver, Sachs, Hirt, and others, have described a condition of meningo-encephalitis as present in these cases, and Wallenburg considered this the primary condition in 14 cases of his collection. Strumpell's theory of an inflammation limited to the gray cortex has been discarded from lack of evidence. Thus it is evident that diseased states of the blood-vessels, their rupture or their plugging, or inflammatory conditions of the meninges or brain, may be the primary conditions in many cases of sclerotic atrophy and of porencephalus ; conditions which vary very widely, and which it is often impossible, clinically, to distinguish from each other. It is also evident that in quite a proportion of cases the origin of the atrophy must be a maldevelopment, whose real reason is wholly obscure.

From this review it is apparent that many of the conditions are of such a nature as to be wholly unaffected by an operative interference. A porencephalic cavity, filled with cerebro-spinal fluid, is not likely to be benefited by any enlargement of the intra cranial space, or by the abstraction of the fluid. In several cases operated upon the withdrawal of this fluid has been followed by sudden collapse and death.[1] On the other hand, there are conditions, such as maldevelopment of the cortex without gross lesion, in which it is possible that anything which may stimulate latent powers of growth, or may remove those influences which interfere with development, might result in improvement. It is to be remembered that the brain is capable of growth and development until the age of fourteen, if not longer, and granting that a stimulus to its growth may be given during childhood, that the arrest of development in many cases might perhaps have been prevented.

The study of the pathological condition therefore does not absolutely contra-indicate the operative interference, although it makes it clear that the lesion in the majority of the cases is one which cannot be improved by any means. If we admit that porencephalus, atrophy from vascular lesion, meningo-encephalitis, and hydrocephalus are incurable, and that hemorrhages cannot be diagnosticated early enough to warrant the removal of the clot before it has caused atrophy from pressure, we have 193 cases out of 343 in which operation would have been futile. This leaves 150 cases of sclerotic atrophy, maldevelopment of the cortex, and cysts, in which it is barely possible that an operation, if it relieved pressure, or stimulated brain growth, might have had some effect. It is only by the latter hypothesis that the apparent improvement in certain cases can be explained.

[1] This number of cases has been gathered from the records of Kundrat, Audry, Wallenburg, Osler, Wilmarth, Feer, Henoch, Hirt, Fowler, Schultze, Sachs, Richardiere, Bourneville, Fisher, and from the American and foreign journals of the past three years, duplicates being sought and excluded.

[1] Cases of Bullard : Boston Medical and Surgical Journal, February 16, 1888. Hammond : New York Medical Journal, August 12, 1890.

The unfortunate fact remains that it is impossible to ascertain the actual pathological condition present without an exploratory operation, as no clinical facts are at our disposal to enable a pathological diagnosis to be made.

A suggestion is here offered incidentally, that when operation is undertaken the surgeon, before opening the dura should, by manipulation or by exploration with a hypodermic needle, ascertain if possible whether a cavity in the brain exists beneath the opening in the skull, and if so avoid opening the dura lest the evacuation of this cavity result in death.

II. **The Results of Experience.**—Let us review lastly the results of the experience of surgeons in the treatment of these cases by operation.

The operation of craniectomy has been done by many surgeons during the past three years, and the results have been reported by several of them, notably by Lannelongue, Keen, Bullard, Oppenheim, Frank, Hammond, Horsley, and Agnew. Many other operators have reported single cases.[1]

The accompanying table of twenty-three cases gives the name of the operators, the journal in which the report is given, the age of the patient, the symptoms for which operation was done, the condition found at the operation, and the result, with the time which had elapsed before the result was reported. Lannelongue's cases are not included in the list. He stated at the French Congress of Surgery in Paris, in April, 1891, that he had operated twenty-five times with but one fatal result, and remarked in general terms that the patients—who were chiefly microcephalic infants or epileptic children—improved after the operation. As more precise facts are needed these cases are excluded from the table.

Table of Cases of Craniotomy in Children.

Reporter.	Condition for which Operation was Performed.	Age (Years).	Condition Found.	Result.	Time of report after Operation.
Bradford and Bullard: Boston Surgical and Medical Journal, February, 1888.	Hemiplegia; imbecility	4½	Porencephalus	Death from shock in twenty-four hours.	
Frank: American Journal of the Medical Sciences, January, 1890.	Double hemiplegia; imbecility	6	Dura thick; brain normal.	Death from shock in three days.	
Bartlett: Hahnemann Monthly, May, 1890.	Hemiplegia; imbecility; epilepsy.	16	Atrophy of motor area	Recovery from operation	10 days.
Oppenheim: Deutsche Medicinische Wochenschrift, May, 1890.	Hemiplegia; epilepsy	12	Cyst and atrophy of the brain.	Paralysis improved, fits less frequent.	2 months.
Hammond: New York Medical Journal, August, 1890.	Hemiplegia; imbecility; epilepsy.	19	Meningitis: porencephalus.	Death from shock in five days.	
Trimble: Medical News, January, 1891	Idiot; had never walked; microcephalus.	3	Dura not opened.	Some improvement.	1 month.
Wyeth: New York Medical Record, February, 1891	Imbecility; microcephalus	11 mo.	Dura not opened.	"Surprising improvement"	1 month.
Anger: Progrès Médical, April, 1891	Imbecility; microcephalus; epilepsy.	8	Dura not opened.	Improvement.	
Maunoury: Progrès Médical, April, 1891	Microcephalus; epilepsy: idiocy.	2	Dura not opened.	Death in twenty hours from shock.	
Maunoury: Progrès Médical, April, 1891	Double hemiplegia; athetosis; epilepsy; idiocy.	4	Dura not opened.	Improved for three months, then all symptoms returned.	5 months.
Heurtaux: Progrès Médical, April, 1891	Microcephalus; epilepsy	5½ mo.	Dura not opened	Death from exhaustion in five weeks.	
Keen: American Journal of the Medical Sciences, June, 1891.	Imbecility; microcephalus; epilepsy.	4½	Dura not opened.	No marked improvement. Second operation three months later; no change.	5 months.
Keen: Loc. cit	Imbecility; microcephalus	1½	Dura not opened.	No improvement. Second operation three months later; no change.	5 months.
Keen: Loc. cit	Imbecility; microcephalus	1½	Dura not opened.	Death from shock in one hour.	
Gerster and Sachs, reported by Keen: Loc. cit.	Imbecility; microcephalus; epilepsy.	4½	Dura not opened.	Death from shock in three hours.	
McClintock, reported by Keen: Loc. cit.	Idiocy; hemiplegia; blindness	3½	Dura not opened.	Improved. "Paralysis almost disappeared."	1 month.
Horsley: British Medical Journal, September, 1891.	Idiocy; microcephalus	3	Dura not opened.	Some improvement.	
Horsley: Loc. cit.	Imbecility; microcephalus; epilepsy.	7	Bone thick; dura not opened	Death from fever on second day; brain normal.	
Willard, reported by Agnew: Univ. Medical Magazine, October, 1891.	Imbecility; athetosis	5	Dura not opened; porencephalus found at autopsy.	Death on third day from scarlet fever.	
Morrison, reported by Agnew: Loc. cit	Imbecility	2½	Dura not opened.	Improved.	
Hammond: Medical News, October, 1891	Aphasia; traumatism; epilepsy	3	Bone thickened; dura not opened.	Cure of aphasia and of epilepsy.	2 years.
Hammond: Loc. cit	Hemiplegia; traumatism; epilepsy at eight years of age.	38	Cyst; atrophy of brain	Death in fifty days from exhaustion.	
Fisher: Medical News, November, 1891	Insanity; epilepsy; trauma at two years of age.	30	Depressed bone; brain normal.	Fits at first fewer; later, no improvement.	2 months.
McBurney and Starr	Hemiplegia; epilepsy.	6	Brain normal	Improvement very marked	9 months.
Hartley and Starr	Imbecility; epilepsy; hemiplegia; aphasia.	7	Brain normal	Improvement in paralysis and aphasia; fits, same.	6 months.

It will be noticed that of 23 cases 8 died. This demonstrates that the operation of trephining is a more serious one in childhood than in adult life. Death has been due in 6 cases to shock from sudden evacuation of cerebro-spinal fluid, or from the severity and length of the operation, and under these circumstances it has occurred within a few hours or days of the operation. In two cases it has been due to exhaustion, and has not taken place within a month of the operation. This is a much greater mortality than occurred in Lannelongue's experience.

Two criticisms must be offered upon the reports of this class of operations. First, they are considered too exclusively from a surgical standpoint, and recovery from the operation may often be misconstrued as recovery from the original condition. Secondly, they are reported too soon after the operation to warrant any very positive statements regarding its permanent effects. In some cases the paralysis has been markedly relieved. In some cases the epileptic attacks have been said to be diminished in frequency and severity, or have been modified in character; but when the undoubted fact is admitted that any operation may modify the course of epilepsy[1] such statements must be subjected to the test of long observation. It will be noticed that Maunoury reports an improvement for three months followed by return of the symptoms. In some cases a marked improvement in the mental condition has been reported, but here it is to be remembered that education and training will do much, and have been attempted perhaps more thoroughly after than before the operation. It is very desirable, therefore, that the medical reports in such cases should be more complete. A careful study of about fifty cases of operation already recorded has not enabled me to reach any conclusion as to the final success or failure in any one case. It is as yet too soon to make a positive statement.

As a further contribution to this subject the two following cases are reported:

[1] For a discussion of the methods and dangers, Dr. Keen's able paper in the American Journal of the Medical Sciences, June, 1891, may be consulted.

[1] See Dr. J. William White on the supposed curative effects of operations per se, Annals of Surgery, August and September, 1891.

Case I. *Hemiplegia, Epilepsy, Mental Weakness—Trephining — Improvement.* — E. H——, now[1] seven years of age, was born without difficulty, and was a healthy baby until five months, when she was suddenly seized with general convulsions attended by high fever and followed by left hemiplegia. For three weeks the temperature varied from 100° F. to 105° F., and convulsions recurred from time to time, the child being unconscious almost all the time and being kept alive with difficulty. Then a gradual recovery began which had continued till the sixth year, when I saw her. She was still markedly hemiplegic on the left side, the face was noticeably affected when she made voluntary grimaces; the arm was moved fairly well, but the hand was useless and the fingers were in constant slow motion of flexion and extension, these athetoses being much increased by any effort with the other hand; the leg was moved well, though she drags the foot a little in walking, and the ankle was quite rigid but not deformed, there being a tendency to talipes equinus. The paralyzed limbs were smaller than the others, but sensation was normal and electrical reactions were but slightly less than on the other side, there being no qualitative change of reaction. Ever since the onset of the hemiplegia she had been subject to attacks of an epileptic character. She had numerous slight attacks daily, lasting a few seconds, in which she seemed alarmed, ran to and grasped someone, saying she felt sick. Since the age of five she has had severe attacks, chiefly at night, in which she cries out and has a short general convulsion, usually more marked on the left side, without biting the tongue or passage of urine. After such attacks she sometimes sleeps, sometimes goes on playing. In the past six months she had also had two very severe attacks of unilateral convulsions, there being a series in each attack. In these the spasm was first limited to the left face, the eyes turning to the left; then to face and arm, then to face, arm, and leg, extending in this order, and finally the entire left half of the body was invaded in each spasm. Each spasm lasted about six minutes, the series lasting an hour and a half, and she was unconscious throughout. After these two attacks she was quite weak for a day or two, and the hemiplegia was more marked and the athetosis was perceptibly less.

She had been petted much, and her parents think this is one cause of her being very fretful, irritable, hard to manage, and difficult to teach. The fact is that the child was deficient in the power of self-control and of voluntary attention, though her perceptions were keen and her mind active. All her sensory powers were perfect.

The increase in the number and severity of the epileptic attacks, and the realization of the mental deficiency of this little girl, led the parents to desire an operation; and with the distinct understanding that no positive result could be assured, Dr. McBurney trephined, at Roosevelt Hospital, on February 10, 1891, at my request. A portion of skull about two by three inches was removed over the middle third of the motor portion of the right hemisphere. This point was selected by reason of the paralysis being more marked in the left arm and hand than elsewhere, because the athetosis was confined to these parts, and hence the unilateral convulsion had affected these parts chiefly. The bone and dura were normal; the pulsation of the brain beneath the area being exposed, as well as the sensation to touch, made it evident that there was no cavity with fluid beneath the dura. The dura was therefore divided, and the brain tissue exposed. The fissure of Rolando, and the anterior and posterior central convolutions were recognized. The brain appeared to be perfectly normal. There was no evidence of the previous occurrence of a hemorrhage, or of meningo-encephalitis, and no trace of atrophy. The dura was then sutured, the bone was not replaced, the wound was closed and healed promptly, and in two weeks the child was at home again. For one month after the operation the hemiplegia was more marked, and the athetosis much less; then the paresis began to improve and the athetosis returned, and nine months after the operation the hemiplegia may be said to be markedly improved, but the athetosis continues. The severe epileptic fits with a cry which occurred nightly, and the Jacksonian fits of which she had had two series in the six months prior to the operation, have not recurred. The *petit mal* attacks continued for two months after the operation, and then began to diminish in frequency. The daily record shows the contrast between March and September. In March she was having two or three attacks daily. In September she had fourteen attacks only, having had none at all during the first twelve days of the month. The parents believe that the mental condition of the child is markedly better, and that she is more capable of concentrating her attention. She has a more intelligent facial expression than formerly, but I am of the opinion that such mental improvement as has occurred is owing to more special and intelligent instruction and management than she had prior to the operation, and to the progress of natural development. It is too soon, however, to estimate this condition satisfactorily.

[1] November, 1891.

During the past nine months she has had three peculiar attacks in which she has suddenly become alarmed, fretful, and appeared to be suffering. At these times the face has been flushed, and the scalp over the opening in the skull bulged perceptibly. She has not lost consciousness and has had no fit, but subsequently has appeared to be very weak, and for several minutes quite unable to move, and for an hour after has complained of tingling sensations in the hand. Whether the opening in the skull has prevented a sudden cerebral congestion from irritating the brain and thus prevented a fit, may be regarded as an open question. That some marked change occurs in the intra-cranial pressure is proven by the marked bulging on each occasion.

Case II. *Imbecility, Epilepsy, Hemiplegia—Trephining—Improvement.*—L. B——, now eight and a half years of age, was born prematurely, and was raised with difficulty. Her mother died of phthisis. At the age of five months she began to have convulsions, which had continued up till the time I first saw her, in April, 1891. She was then having twenty fits in a day, each lasting from two to five minutes. At one time she had gone a month without a fit under bromide treatment. The girl had always been an imbecile, had failed to develop properly, and appeared like a child of four years. She was very microcephalic, all the measurements being much below the normal, but the skull was not asymmetrical. She had learned to walk and to talk, but suddenly, in November, 1890, after a fit was found to be aphasic and hemiplegic on the right side. The aphasia was complete when I saw her, having persisted for five months. She understood what was said to her, obeyed commands, but said nothing. The hemiplegia had improved, but her right hand was useless and in a state of athetoid movement. It was less sensitive than the left hand. Her head was in constant rotary motion. Examination showed a right bilateral hemianopsia. The aunt had noticed an increase in the mental dulness, and said that the child was too stupid to cry.

While the appearance and the actions pointed to a condition of imbecility due to microcephalus, it was thought that the sudden onset of hemiplegia and aphasia, with hemianopsia, indicated either the occurrence of a hemorrhage, or beginning tubercular meningitis. With a view to the possibility of removing a clot, the child was sent to Roosevelt Hospital, where, at my request, Dr. Hartley operated upon her on May 15, 1891. A piece of bone, about two inches in diameter, was removed from the skull over the lower part of the motor area and Broca's convolution, and this opening was then enlarged upward and backward. There was no bulging of the dura, and no evidence of increased cranial pressure. When the dura was divided the cortex of the posterior

part of the third and second frontal convolutions, and the lower half of the anterior central convolution, were exposed to view and recognized. No clot was found, no evidence of meningitis, and the brain presented a normal appearance. The wound was therefore closed, the bone being left out, and it healed promptly without any complication. For six weeks after the operation no change was apparent in the condition, and the fits continued as before, from six to twenty daily. Then a marked improvement began. At present, six months after the operation, the child talks freely, names objects at once, can answer simple questions, and sing children's songs. The hemiplegia has disappeared entirely, but effort with the left hand produces associated motions in the right hand. All rotary movements of the head have ceased. Sensation seems keen in the right hand. There seems to be traces of right hemianopsia, but she is watchful of tests, though too stupid to give any accurate replies. She has been taught to keep herself clean, and is certainly more observant and obedient than formerly, though still imbecile. She is still having fits, but rarely more than six daily. They do not yield to bromide or to chloral. I am wholly unable to explain the very marked improvement which has followed the operation, especially as there was nothing accomplished by it at the time in the relief of local disease, or of general pressure.

In both cases it is interesting to observe, that no gross defect of brain-substance, no marked atrophy was discovered, and if lesions were present in the brain, they must have been of microscopic character. Is it possible that there was in both cases an arrest of development, rather than an actual lesion, and that the effect of the operation was to stimulate the growth of cerebral tissue?

From this review of the clinical types of cerebral atrophy in childhood, of the pathological conditions producing these types, and of the results of surgical treatment by craniotomy, the following conclusions may be drawn:

1. Hemiplegia, sensory defects, and imbecility occurring with or without epilepsy in children, are chronic diseases, incurable by medical treatment. Any means which may be legitimately used to save the individual from a life of invalidism, and to take the burden of his care from the family, is to be employed.

2. The pathological conditions producing these symptoms may be either gross defects and atrophies of the brain, or an arrest of development in the cerebral cells, without any change which is apparent to the naked eye.

3. It is at present impossible to determine absolutely the pathological condition present in any given case, without an exploratory operation.

4. Such operations are not without danger, but if caution is used in opening the dura, and if the operation is made as short as possible, the dangers are avoided.

5. When manifest atrophies are present the operation will not produce any result. When the condition is one of arrested development of cerebral tissue, it may prove of service. When clots, cysts, or tumors are found and removed, the chance of recovery is increased. When the skull is markedly microcephalic from early union of the sutures, the increased space given to the brain by the operation appears to stimulate its growth and development.

6. Epileptic attacks are frequently reduced in frequency and modified in character by craniotomy. When the opening of the skull remains covered only by the soft tissues, it appears to act as a safety-valve, allowing changes in the intra-cranial contents to occur without producing pressure upon the brain.

7. While hemiplegia, aphasia, athetosis, and sensory defects have been relieved by operation, it is as yet impossible to predict to what extent imbecility may be relieved.

8. Reports of cases should be made in full, and not within six months of the time of operation, as conclusions cannot be reliable unless reached from long observation.

A CONTRIBUTION TO THE TREATMENT OF MALIGNANT GROWTHS.

By JOSEPH DRZEWIECKI, M.D.,

LATE PHYSICIAN IN THE UNIVERSITY CLINIC OF THE HOLY GHOST HOSPITAL, WARSAW, POLAND.

Among the diseases with which mankind is afflicted cancer plays an important rôle. This disease has lately spread more and more, and statistics show that the number of deaths from cancer increases every year. This increase the anti-vaccinationists refer to obligatory vaccination, proving by their figures that from the moment of introducing preventive inoculation of small pox in the West Indies and the South Seas cancer became a more frequent disease.

It is not our intention to examine in this article the causes influencing the frequency of cancer, and we quoted the above opinion only because of its originality. Our aim is to look over some facts concerning the treatment of cancer, and to deduce from them the road that we must follow in order to conquer the disease.

Up to the present time the only effectual remedy for the disease has been the knife. It, however, can be useful only when it is applied just at the beginning of the disease; and as patients affected with malignant tumor for the most part call the doctor only when the disease has become generalized, the operation as a remedy is palliative only, but of radical recovery there can be no question. The statistics of operation for cancer are not at all equivocal, and for this reason some surgeons refuse to regard it as a remedy. Besides that, this treatment diverges too far from the so-called "ideal therapy," the aim of which is not only to restore the health of the patient, but also to retain the integrity of his tissues. Therefore the question arises: what way must be kept to make the fight with this disease possible? Nature, like a kind mother, has not neglected to indicate the way here as everywhere else. We are well familiar with the clinical fact that, as soon as a patient affected with malignant growth is attacked with erysipelas, the tumor either disappears entirely or at least considerably diminishes in size.

Let us look over the literature of the subject during recent years.

Dr. Biedert,[1] of the Hegenauer Hospital, has published an interesting case showing the effect of an attack of erysipelas on the course of a slowly growing sarcoma. The patient was a girl, eight years of age, who presented herself two years before with a tumor the size of a hen's egg, on the left tonsil; an operation was advised, but refused. A year and nine months later the child was again brought, and the growth was then found to involve the whole posterior half of the buccal cavity, including the tongue, which, moreover, presented an ulcerating mass at its apex on the left side; it had also involved the nasal cavity and the right eyelid. The general condition was serious, there being inability to swallow, and great dyspnœa, which was so urgent that tracheotomy was performed. An attack of erysipelas supervened in three days, beginning in the neighborhood of the right eye. The attack was severe (temperature 104° F.), and was allowed to run its course for six days, at the end of which time the growth had disappeared in every part, except two nodules, of the size of a pea, in the right upper lid and the nostril; these were afterward excised. There was no infiltration in the throat and tongue, but much puckering and scarring. Some months after there was no recurrence of the growth in any part.

Roman Iasinski, in a Polish paper,[2] has described a case in which a lymphoma, complicated with erysipelas, disappeared entirely, and Professor Billroth[3] refers to Professor Volkmann, who witnessed the disappearance of a fibroma, *i.e.*, a tissue which comparatively is very dense.

after an attack of erysipelas. Even upon tuberculous tissue erysipelas extends its salutary action. Dr. Wailel[1] has published a case of a patient with a very pronounced family history of tuberculosis, who had exhibited for about two months distinct evidences of beginning phthisis pulmonum. There had been fever, sweats, expectoration which was sometimes bloody, emaciation, dyspnœa, and progressive weakness. Physical examination revealed some depression and diminished expansion of the upper part of the right side, decided dulness on percussion, increased vocal resonance, and somewhat bronchial respiration, with a few râles. During five weeks of observation the physical signs grew worse, the left side began to be involved, the amount of expectoration increased, and there was fever in the evening. At this period the patient developed a severe attack of facial erysipelas, spreading over the whole head, and accompanied by rapid pulse, high fever, delirium, and great prostration. This condition lasted a week, and after recovery there was a surprising change in the pulmonary symptoms. Fever and insomnia permanently disappeared, and a prodigious appetite developed. In three months the patient was perfectly strong, and able to undertake hard outdoor labor. Nearly a year after the first observation, the author again examined his quondam patient, and found scarcely a trace of the former pulmonary lesions.

Dr. Grivet[2] relates a whole series of cases of lupus cured by erysipelas, and this kind of happy complication produced by erysipelas, and its salutary effect upon the course of incurable or obstinate diseases, was selected by Dr. Daniel Chambon[3] as the subject for his inaugural dissertation. From the above properties of erysipelas physicians have more than once endeavored to draw profit and use them for therapeutic purposes. The question has been raised and variously answered as to the justifiability of artificially producing erysipelas in desperate cases.

Ricord and Deprés, in France, were the first to carry this procedure into execution; and Busch, in Germany, did the same with astonishing results. When Fehleisen succeeded in obtaining pure cultures of the cocci of erysipelas, the experiments with inoculation of erysipelas to cure malignant tumors began to multiply. Fehleisen[4] himself reported seven cases in which inoculation had been performed, namely: in one case of numerous fibrosarcomata cutis; in three of carcinoma mammæ inoperabilis; in one of sarcoma of the right eye (two inoculations); in two of lupus. Although the results of this treatment were not very splendid, yet it must be owned that almost in every case a slight diminution of growth could be observed. The best results, however, were obtained in cancer of the breast, where in one case complete recovery was effected, and in two considerable diminution in the size of the tumor. Further the adoption of this measure is recorded by Dr. Axel Holst,[5] of Christiania. The patient was a woman, aged forty, who had a recurrent carcinoma of the right breast, for which she declined further operation. In a few months the cancer had infiltrated the greater part of the surface of the right half of the chest, forming a red brawny mass, with a raw surface, nodulated on the margins, while the axillary and clavicular glands were much enlarged, and the arm was œdematous.

In spite of the unfavorable aspect of the case, it was decided to try the effect of erysipelas inoculation. After twenty-one hours the patient had a series of rigors followed by the appearance of an erysipelatous blush, which, within thirty hours extended over the whole right arm, and later spread to the left side of the chest, back, and even to the left arm. In a few days the erysipelatous area was confined to a margin from three to six centimetres in width; and on the seventh day the fever, which throughout had not been high, fell by crisis. At the end of four months and a half the erysipelas still persisted on the right arm, but the patient had manifestly lost ground. During the first two months and a half the progress of the cancer appeared to be arrested, and for some distance the wound had healed over, while the induration had become less marked. The inoculation had, then, prolonged life, for the arrest in the progress of the cancer was marked; but the patient, who formerly was in good health, lost her strength and appetite, which before were perfect. The loss of strength the author ascribes to the inoculation, and concludes that the application of this procedure requires some courage on the part of the physician.

Dr. Tanicke,[1] in *Wiener med. Blätter*, reports the case of a woman, forty years of age, affected with recurrent cancer of the breast; it was a *casus inoperabilis*. In spite of excessive pain the strength of the patient was satisfactory and the internal organs were healthy, and this was the reason that inoculation of erysipelas was made. Within eight hours from the time of inoculation, she had violent chills, and the temperature rose to 40.2° C. Three days after the inoculation she died in collapse. Notwithstanding that the time was so short the tumor had softened and diminished, and one nodule under the collar-bone had disappeared entirely. It could be noticed with the naked eye that the growth had softened. The histological examination, made by Professor Neiser, proved that the tumor was an epithelioma. The author is of opinion that the above observation gives eloquent testimony to the danger of artificial inoculation of erysipelas. Of another opinion is Dr. Kleeblat,[2] who has seen only positive results and not any dangerous consequences in the treatment of three cases of malignant tumors by inoculation of erysipelas.

This method of treating malignant growths, praised by some and by others regarded as not suitable, could not attain the right of citizenship in science for two reasons: First, that erysipelas in itself is a serious disease, sometimes bringing to the grave even the strongest organisms; second, that we are not able to govern its course, and therefore by application of such an heroic remedy we might too much expose the patient to danger, who is already, as a rule, enfeebled. The fact, however, of the salutary effect of erysipelas on the course of growths in general remains, and involuntarily rises before our eyes, especially in such desperate cases where the doctor called to the patient is able to do nothing but offer some consoling words and administer narcotics.

Although the inoculation of erysipelas should be dispensed with, yet the toxine, excreted by cocci of erysipelas, as entirely susceptible to accurate doing, should be tried, and in this manner the fact of the healing action of erysipelas may be rendered therapeutically available.

I believe that every physician may undertake experiments with the toxine of erysipelas in cancer with a quiet conscience, because they will be based upon certain facts, and the plan and conductive idea will be transparent in them. Thus, as much as the experiments in the inoculation of cancer upon patients in sleep were condemned by all as being aimless, and made only in order to affirm once more what already had been proved by Weber, on dogs, and Henau, on rats, so much again the experiments with toxine of erysipelas, as based upon certain facts and made with an aim, should be accepted with appreciation.

As I do not occupy myself with bacteriology, and have now no occasion to betake myself to the above kind of experiments, I throw out the idea with the hope that perhaps the bacteriologists will take it in consideration, and who knows whether, following this road, we shall not reach the fields where an abundant crop awaits us.

SUPPURATIVE PERITYPHLITIS—REPORT OF CASE—RUPTURE INTO BLADDER AND RECTUM—OPERATION—RECOVERY.

By M. T. SCOTT, A.M., M.D.,

LEXINGTON, KY.

On October 2, 1891, I was requested by Dr. W. H. Fish, of Nicholasville, Ky., to visit with him a patient forty miles from this city. The history of the case before my visit was about as follows :

P. H. McG——, aged thirty-three, white; minister, American by birth, married; had never been a stout man. Had suffered severely for years from malaria contracted in the swamp lands of Mississippi and Louisiana. He had also had repeated, but not profuse, hæmoptysis.

For some months prior to September 8, 1891, he had been in unusually good health. He had gone, some weeks previous, beyond Mt. Sterling, Ky., to conduct a "protracted meeting" at a country church. On the afternoon of the above date he had walked two miles, and had also amused himself by cracking stone for a macadamized turnpike, by the roadside. He ate freely of grapes, as was his custom. In the evening he took a hearty supper and preached a sermon about two hundred yards from his lodging-place. During the night he was awakened by an intense pain in the right iliac region, which radiated over the entire abdomen. He vomited freely, and had a copious discharge from the bowels; neither, however, afforded him any relief. The following morning a physician was summoned, who administered morphine hypodermically. For the next eight days, opiates and salines were continued; a dull, painful induration occupying the right iliac fossa during that time. His bowels were kept open. Pulse and temperature remained high. On the ninth day of his illness, his family physician, Dr. Fish, was summoned. By his advice, one ounce of castor-oil was administered. A few hours later, a large enema was given—after great straining, a mass of very hard fæces was voided. The patient expressed himself as greatly relieved, remarking that he had been in labor more than a week, but was now delivered. Purgatives, morphine, and blisters over the iliac hardness, which was not reduced by the action referred to, constituted the treatment until September 29th. The temperature, meanwhile, ran to 102° and 103° F, and pulse as high as 120. Chilly sensations and profuse perspirations were of daily occurrence.

On the above mentioned date the patient felt a sudden desire to empty his bladder. He arose, and while straining violently, felt something give way. This was immediately followed by an escape of gas, pus, blood, and feculent urine from the penis. The escape of gas making a whistling sound. The abdominal fulness subsided somewhat; the temperature and pulse fell to about normal. The urine was voided very frequently, was thick, turbid, scanty, and presented a distinct feculent odor and sediment.

I first saw him in the afternoon of October 2d. He was extremely emaciated and sweating; pulse, 93, temperature, 101½° F. The abdomen was tender, but not extremely so, greatest sensitiveness being in the right iliac region and to the left of the navel. An ill-defined dulness and sense of resistance was found over the head of the colon. He was but slightly nauseated, taking his nourishment fairly well.

In the consultation room, I advised an operation as his only hope of recovery. The symptoms not being very threatening, and he, in the country, among strangers, I urged his immediate removal to the Protestant Infirmary in this city, where he could have the advantages of accomplished trained nurses and an admirably conducted hospital.

The journey was arranged for the following day. Four hours previous to his removal, while straining at stool, he felt another sensation of giving way; this was followed by about three ounces of pus from the rectum, and then a movement.

The journey to this city, five miles of which was on a wagon and thirty-five miles in the cars, was devoid of interest. The motion of the rapidly moving express train occasioned much pain. He entered the hospital at 6 P.M., October 3d. His pulse was 93, temperature, 101½° F. His condition was noted as "extreme emaciation, anxious countenance, general abdominal tenderness, frequent passages of scanty, turbid, and feculent urine, much dysuria." On the following morning, at a consultation with a number of my professional friends, a digital examination detected the point of rupture into the rectum, immediately above and to the right of the prostate.

At 10 A.M., October 5th, the "A. C. E." mixture was administered by Dr. H. M. Skillman. In the operation, I was assisted by Drs. Fish, Falconer, Barrow, Bryan, Moore, and others. As no well defined fluctuation or resistance was found, I made a median incision three inches long, midway between the umbilicus and pubis. The entrance of the peritoneal sac was accompanied by a copious flow of gas and feculent pus, probably more than a pint of the latter. Adhesion had cut off the lower peritoneal pouch from the general cavity. Coils of small intestine floated in the pus-cavity. The perforations into the bladder and rectum were found in the vesico-rectal fold near the bottom. The tract leading to the cæcum was not found, and no attempt was made to break up adhesions, lest the general peritoneum might be infected. The sac was thoroughly cleansed, and large parallel glass and rubber drainage-tubes reaching to the bottom of the abscess pouch were inserted. The operation lasted thirty minutes. The shock was marked. Hot bottles and whiskey hypodermically were freely used. Reaction came on slowly. Hot water, in small quantities frequently repeated, allayed nausea. The catheter was used but once, four hours after the operation; the urine was then thick, offensive, and feculent. The bladder was subsequently emptied voluntarily, at short intervals, with great pain. Twenty hours after his removal from the table, all odor from, and feculent sediment in, the urine ceased, and at no time returned. The vesical irritability and tenesmus gradually abated. The fluid was withdrawn from the tubes at frequent intervals. The cavity was frequently washed out with hot water. Stimulants, whiskey, egg-nogg, and beef-tea, were commenced in twenty-four hours. Small quantities of morphine were used hypodermically to quiet his bladder irritability.

On the morning of the second day, free purgation was induced by three one-drachm doses of magnesium sulphate, repeated at intervals of two hours. A small quantity of glycerine was also thrown into the rectum to soften down any hard fæces that might undo any reparative action about the rectal opening.

On the afternoon of the fourth day his temperature rose to 101° F. and the pulse to 110. Tympanites was marked and distressing. A blush appeared around the wound and the patient became restless and anxious. The stitches were cut, adhesion broken up, and the wound was thoroughly cleansed. A small undraining pocket of feculent pus was found to the left of, and above, the incision, behind the anterior abdominal wall. This and the wound were packed with iodoform gauze. Salol was also ordered in five-grain doses every four hours. A marked improvement followed this procedure.

The rubber drainage-tube was removed on the seventh day. On the fourteenth day, a full dose of calomel was given to correct a transient digestive disorder; six hours later the abdominal compresses were found saturated with bile. The glass tube was replaced on the fourteenth day by a rubber one; this was gradually shortened, and gave place to smaller sizes, until its final removal on the fortieth day. On the twenty fourth day an aggravation of symptoms suddenly arose. Pulse and temperature reaching 124 and 102° F., respectively. Two days later, about half an ounce of pus welled out of the tubes.

After this, what little iliac tenderness had all along existed subsided, and the patient convalesced rapidly and uninterruptedly.

On October 30th, during the relapse just referred to, a portion of mucous membrane four by six inches was voided per anum. It was firmly organized, and, so far as I could determine, was from the cæcum.

On November 25th, the patient left for his home, much improved in flesh. He had for days prior to his departure been walking about the hospital, going up and down stairs. No lameness or tenderness existed. His bladder and bowels acted painlessly and voluntarily at regular intervals. The iliac hardness was constantly diminishing. He was advised to take compound syrup of the hypophosphites as a tonic for some time. I might add that the administration of the remedy was commenced ten days after his admission to the hospital. The wound had entirely healed except a small granulation where the tube remained so long. There was no sinus. I have recently heard from Dr. Fish that the wound cicatrized promptly, and that no hernial tendency existed. At no time while the patient was under my observation did he have any cough. Inspection, percussion, and auscultation of the chest failed to reveal any anomaly.

Remarks.—That perityphlitis or peri-cæcal cellulitis is of much more frequent occurrence than was formerly supposed cannot be doubted. Modern methods of diagnosis have cleared up many cases that formerly would have been vague and uncertain. Practitioners of medicine as well as of surgery frequently encounter this malady. Thanks to the instruction of those who have taught us that the dangers of opening the abdominal cavity are often less than those of what had erroneously been termed conservatism, its treatment has been placed on a practical and scientific basis.

While authorities are divided as to the advisability of surgical interference in perityphlitis in general, they, of course, agree that where pus has formed it should be evacuated. Nearly all cases of pericæcal cellulitis or appendicitis terminate in suppuration, sooner or later.

While nature unaided may empty the abscess into the intestine or externally, still the danger of rupture into the peritoneum is great, and even if the pus is voided, still the peril from burrowing, absorption, bad drainage, and exhaustion is by no means small. Howe, in the second volume of the "International Encyclopædia of Surgery," says that if the abscess rupture into the peritoneal cavity, it is always fatal. He adds, "When the bladder is perforated, which is a rare occurrence, pus in considerable quantity may be distinguished in the urine."

The Rarity of Rupture into the Bladder.—While all authors either state or imply that a perityphlitic abscess may burst into the bladder and rectum, still very few cases are recorded of rupture into the former viscus. In the New York Medical Record of October 17, 1891, mention is made of such a rupture by Dr. Cotton, in the report of the "Transactions of the Canadian Medical Association." We can readily see, from a study of the pelvic anatomy, why this rupture is rare. Less resistance is encountered in other directions.

It does not seem possible for a spontaneous rupture into the bladder to afford sufficient drainage. The opening is usually small, a violent cystitis must ensue, and there is great danger of some intestinal contents forming the nucleus of stone, even if the more imminent perils are avoided.

Suddenness of Attack.—The disease under consideration usually, even in the most acute cases, has a period of malaise, tenderness, and vague pain about the cæcum, radiating over the abdomen, before rupture of the sac. This patient, a remarkably intelligent man, by the way, had been in unusually good health, had never had any discomforts about the caput coli; in short, had no intimation whatever of the storm that was brewing until the onset of the symptoms was so violent as to be explicable only on the theory of rupture.

Long Use of the Drainage-tube.—Occasional elevations of temperature and pulse, culminating in more copious pus discharges, made me very loath to give up drainage and allow the external wound to heal, lest some accumulation might remain undrained.

Coils of Intestine in the Sac.—The pus-sac in the case under consideration was not formed by the pushing aside of the intestines, but was composed of a large section of the peritoneum. Coils of the ileum, as has been stated, were floating in the feculent pus. It seems marvellous how nature could so interlace these organs, ever moving and changing their shape and relations, with a protected barrier which so securely presented general peritoneal infection.

Conduct of the Drainage-tube.—The abdominal compresses for the first three weeks were frequently saturated with a clear fluid with a strong urinous odor. At no time, however, was the fluid withdrawn from the cavity of a similar character. While the vesical rupture was from the peritoneum into the bladder, still, after the first twenty hours at the farthest, the leakage was from, and not into, the bladder. No evidence of intestinal leakage was found after the bile-staining of the dressings on the fourteenth day. Whether this biliary matter came from the original cæcal opening or through the rectal perforation, I am unable to say. The fluid from the drainage-tube frequently had a musty, intestinal odor, almost feculent. This, however, does not impress me as any evidence of leakage, such an odor being common about any pus from near the intestinal tract.

When to Operate.—It does not seem to me proper to specify any special day on which to operate. No two cases progress with the same rapidity. Dr. Gregg Smith's advice, as contained in his "Abdominal Surgery," is as follows: "Consecutive evening temperatures, for four or five days, rising over 102°, would seem to justify operation. If the patient is losing ground, if hectic supervenes, possibly with rigors, and generally if the condition seems to be drifting into one in which operation would be dangerous to life, then we should interfere." Unquestionably, the proper time to operate is as soon as pus has formed, before the abscess has ruptured. The giving way of the sac, and the diffusion of pus, changes the entire aspect of the case.

An insidious malady has become a desperate extremity. Shock is frequently profound, vitality is reduced, and the recuperative forces are sapped. Many surgeons have to deplore cases that were deferred. I know of no one having recorded himself as a mourner over an operation done too soon.

What Incision Should We Make?—Nearly all writers favor the lateral cut, as affording most ready access to the site of the disease, and if, for diagnostic reasons, the median incision is done, it is probably wise to supplement it by the iliac opening. I did the central operation, knowing that I had the pelvis to drain. Notwithstanding the recovery of my patient, I have at times thought that it might have been wise, had I made a secondary exploration over the appendix; by so doing I could probably have determined the exact site of the original lesion, an investigation that was denied me, except by an unjustifiable breaking up of adhesions. My patient was in an extreme condition; his vitality was so low that I did not dare protract the manipulation or anæsthesia. That my patient would have died if left to nature, I am quite sure. He was emaciated to an extreme degree, and was suffering from marked sepsis, after both openings had occurred. After the bladder rupture there was a temporary amelioration; it did not last long, however. The vesical tenesmus was intense and exhausting. The pus-pouch was large, and was extending behind the anterior abdominal wall, to the left and above the umbilicus. That it was not draining was clearly shown by the large quantity of fæces and pus found in the sac at the time of the operation.

In conclusion, I feel that I would be ungrateful did I

not express my sincere thanks to the trained nurses, Miss Frantz and Miss Stephens, who aided so materially in the restoration of the patient's health. Their care was most gentle, skilful, diligent, and conscientious.

THE MANAGEMENT OF LABOR WITHOUT VAGINAL EXAMINATIONS AND WITHOUT PROPHYLACTIC VAGINAL DOUCHES.

By JULIUS ROSENBERG, M.D.,

NEW YORK.

In this paper I wish to prove two things: 1st. That vaginal examinations are not without danger, and ought to be supplanted by abdominal palpation in the majority of cases. 2d. That vaginal douches are unnecessary in normal labor, and are frequently even harmful.

In discussing these points I will not advance theories, but will give figures and facts; and while it is true that statistics can often be arranged to prove anything, we have so far nothing better to take their place.

Döderlein reports three cases of puerperal infection out of Zweifel's Clinic in Leipzig.[1] These cases were examined by one nurse only, at intervals of from three to eight hours. Investigation has shown that the rigid antiseptic rules of that institution were thoroughly carried out by this nurse. The second case died of puerperal septicæmia eight days post partum, the other two women made a slow recovery from the same malady. It was found that the first case admitted was suffering from a purulent conjunctivitis, and that she must have infected her genital tract prior to labor with her own fingers. It was also demonstrated that even scrupulous disinfection of the fingers after each examination does not give absolute security against the transmission of infection from one person to the other. As the labor was normal in all these three cases vaginal examinations could have been dispensed with, and thus infection avoided.

Veit[2] remarks that it has been demonstrated without a doubt, that infection from the micro-organism normally present in the vaginal secretions is extremely rare. In nearly all cases infection comes from without, either through the unclean examining finger, or infectious material is carried from the external genitals into the vagina and cervix. Hegar[3] has cautioned against frequent vaginal examinations, the external examination should whereever possible displace them.

Winkel remarks[4] that while making an internal examination of a woman in labor, we must remember that, owing to the vascularity and fragility of the parts, there is always imminent danger of the exploring finger inoculating infectious material into the tissues.

The principal danger for the woman lies in the vaginal examinations, because they expose her to two sources of infection: first from without by the unclean examining finger; second, by the aseptic finger introducing infectious material from the vagina into the uterus through the os.

I believe with Berczellen[5] that the great majority of post-partum diseases could be traced to vaginal examinations as their cause; he says: "External examination is in the majority of cases sufficient to establish the correct diagnosis, and enables us also to follow labor through its various stages."

Leopold[6] reports 919 cases in which neither vaginal examinations were made, nor a single douche administered. In 12 of these cases (1.3 per cent.) was there a rise of temperature, which in 10 (1.09 per cent.) could be traced to causes not referable to the act of labor. Thus. in only 2 cases out of nearly 1,000 was there infection acquired through parturition, and even these were of a very mild character, terminating in speedy recovery. I have failed to find in the literature results equally brilliant.

Pavlik[1] speaks favorably of the value of external examination. He says: "Through it alone we can make the diagnosis of transverse or longitudinal position, whether the breech or the head presents, and whether the head has entered the true pelvis or is still movable above the linea innominata."

Sänger, of Leipzig, remarked at the last gynecological congress in Bonn, how frequently vaginal examinations were made by the general practitioner shortly after he had incised an abscess or explored a cancerous ulcer. Even should he disinfect his hands thoroughly, which surely often is not the case, he is very liable to deposit infectious germs into the genital tract.

It is but six years ago that Credé first urged the point that abdominal palpation ought and could displace the vaginal examination in a number of cases. In his book "Gesunde und Kranke Wöchnerinnen," he writes: It has always been my aim to perfect myself in the various methods of making the correct diagnosis in a case of labor by abdominal palpation alone. I have the absolute conviction that the vaginal examination which, until now, is the only accepted method, can be, and should be, displaced in the majority of cases by the external examination. The slightest exploration of the genital canal can injure the tissues, and once the continuity destroyed, the gates to infection are open."

We owe Credé three great innovations, every one of them will stamp him forever a public benefactor. His method of managing the third stage of labor is adopted by all civilized nations, his investigations as to the pathology and prophylaxis of ophthalmia neonatorum have resulted in the preservation of the eyesight of thousands of infants, and many more women will enjoy life and health when once the pernicious practice of needless and frequent vaginal examinations becomes a thing of the past. The student must be taught the method of abdominal palpation in a thorough manner, he must learn that he has chiefly to rely upon this for making a correct diagnosis, and that vaginal examinations are to be resorted to only in doubtful cases. If this were more widely adopted, the material, to which now but few have access, could be used to advantage by many.

In the Royal Maternity at Dresden, twice a week, all waiting women are examined by the Director, Professor Leopold and his assistants, by abdominal palpation, everyone writes down his diagnosis as to whether primipara or multipara, time of gestation, size and position of child, and location of placenta; afterward the diagnosis is compared, and it is but seldom that difference of opinion exists. I have delivered one-third of my cases (much over four hundred) without making a vaginal exploration, and now reserve this method only for exceptional cases.

What are our reasons for making a vaginal examination?

First, we want to know whether labor has commenced. The external method will answer this question perfectly; it shows the height of the fundus, the position of the child, and the presenting part. By observing the woman, we can learn the stage of labor, and by examining the bedcloth the nature of the vaginal discharge, and whether the membranes are still intact. Auscultation shows the condition of the child, and observation of pulse and temperature that of the mother. If all this is normal, is it not only frivolous curiosity which induces us to to subject the woman to the dangers of a vaginal examination? During the expulsive stage there is but seldom an indication for a vaginal exploration, and then generally the question of operative interference arises.

Briefly stated, the indications for a vaginal examination are as follows:

a. *General Disturbances.*—1. Fever and abnormal pulse. 2. Eclampsia and nephritis.

[1] Archiv für Gynecol. vol. xl.
[2] Der Frauenartzl, 1891, p. 395.
[3] Volkmann's Vorträge. No. 351.
[4] Lehrbuch der Geburtshülfe, p. 86.
[5] Centralblatt für Gynecol., 1891, No. 33.
[6] Leopold und Goldberg: Archiv für Gynecol., vol. xl.

[1] Wiener med. Blätter, No. 21.

b. *Local Disturbances.*—1. Protracted preservation of membranes. 2. Discharge of blood from the genitals. 3. Excessive severity of pains. 4. Uterine inertia. 5. Protracted labor.

c. *If the abdominal examination shows:*—1. Abnormal position or presentation. 2. Abnormal distention of lower uterine segment, threatening rupture of the uterus. 3. Abnormality of the fœtal heart-sounds. 4. If the head remains movable above the pelvic brim in a primipara or in a multipara after rupture of the membranes.

If these rules are adhered to, the number of cases in which a vaginal examination becomes necessary will be about one-third.

It must be the object of the obstetrician to diminish the yet comparative high mortality and morbidity, and I believe that by diminishing the frequency of vaginal examinations a great step in the right direction will be made.

Just as little as a surgeon introduces his aseptic probe into a wound without proper indications, just as little is the obstetrician permitted to introduce his fingers in the genital canal without necessity. The fact that a woman is in labor is no indication. Do we use a speculum or uterine sound in every gynecological case, if the combined method of examination has given satisfactory results? Why then are obstetrical examinations considered incomplete when not one or several vaginal examinations are made?

I will now briefly relate how I employ abdominal palpation; it is the method taught by my esteemed teacher, Professor Leopold. He uses four methods (Griffe). Gentleness should always be preserved as an undue amount of pressure results in exciting uterine contractions; during those the examination must be interrupted for the time being.

The woman lies upon her back, with her limbs extended, the abdomen is exposed from the symphysis to the ensiform cartilage.

First. The physician sits at the side of the woman, places both hands slightly flexed, so as to correspond to the convex surface of the uterus, upon the abdomen, and gradually carries them upward toward the fundus; this reached, the failure of resistance is noticed. This teaches us the size of the uterus, time of gestation, whether the child is in longitudinal or transverse position, and whether head or breech occupy the fundus. The uterus is recognized by its intermittent contractions. Care should be exercised not to mistake the bladder for the uterus, therefore the former must always be emptied prior to an examination.

Second. The hands are placed at each side of the uterus; then under one hand we feel the arched back, under the other the small parts corresponding in position to the abdominal surface of the fœtus. When the abdominal walls are thin, the different parts can be felt with surprising clearness.

Third. The fingers of the right or left hand are spread as much as possible, and the presenting part is seized between thumb and middle-finger. If it is round and hard it can only be the head, which can be grasped like a cannonball and moved if above the pelvic brim. The breech is softer, and its surface more irregular. Can no presenting part be felt, then we must look for the head on either side. If the outlines of the presenting head or breech are indistinct, then we are to be suspicious of placenta prævia.

This third method is very valuable in all cases where the presenting part is yet in the entrance of the pelvis; a practised examiner can also locate, through this alone, where the occiput and where the chin point to.

As labor is more advanced, the fourth step will be: The physician takes his place at the bedside, turning the back toward the patient's face. The hands are placed in such a manner upon the patient's abdomen that the fingers are directed toward the cervix. During the intervals of pain the hands are pressed down deep into the pelvis and the presenting part is grasped. The head is again recognized by its peculiarities.

The presence of small parts in close proximity to the abdominal wall, indicates that the back of the child is directed toward the sacrum. Descent of the fœtus is often prevented by abnormalities of the pelvis, in these cases the contraction ring can be felt by abdominal palpation, and thus the danger of a rupture of the uterus by timely means be averted.

Auscultation should always be associated with abdominal palpation to verify our diagnosis, and for reasons previously mentioned. With heart-sounds to the left in maximum intensity the back of the child is directed to the left. When the back is posterior the heart-sounds are loudest in the axillary line and in breech presentations they are heard at a higher level.

All these points of information can be gotten even by the comparatively inexperienced after but little practice; no danger arises for the woman, and her sense of modesty does not need to be so often shocked.

What, now, are the advantages of vaginal examinations?

In the opening stage they reveal but little, only a small part of the presenting part is in our reach, and sometimes the cervix is so directed as to be almost inaccessible. That there is always danger of injuring the tense membranes, or that they prevent every satisfactory examination, is equally well known; therefore we lose nothing and gain much by diminishing the frequency of vaginal examinations and laying more stress upon abdominal palpation.

Obstetrical antisepsis was first brought into use by Semmelweiss, of Vienna, as is well known, when he introduced the disinfection of the hands with chlorine water, in 1847; it resulted in lowering the mortality from puerperal fever, from 12.24 per cent. to 1.27 per cent. A new impetus was given by the investigations of Lister. The excellent results which his methods had given in the treatment of wounds, and the prevention of wound-fever, were also thought applicable to the obstetrical practice. It was the same with this as with every new discovery, the zeal to gain all its advantages carries us beyond the point. Investigation had shown that the genital canal contained micro-organisms and therefore its disinfection was deemed necessary to the prevention of puerperal fever. Carbolic acid sprays and all the paraphernalia of Listerism were brought into use, and eminent men everywhere thought it requisite that the parturient woman be prepared as for a capital operation. I only need to refer to the famous discussion between Professors Thomas and Fordyce Barker, in the Academy of Medicine, regarding the prophylaxis and nature of puerperal fever. Barker remarked that if an ordinary case of labor must be treated as if she had to undergo a laparotomy, "to save thousands of lives which are now lost, and to spare thousands of desolate homes the sorrow of losing their female heads, then the State should make child-bearing a penal offence for all those families who do not have sufficient income to carry out all these requirements."

The extensive antiseptic measures then advocated did not only do any good, but I am sure this unnecessary meddling had often the opposite effect. The first statement is borne out by the observations of Lusk; he says: "In lying-in hospitals, where I have seen many epidemics of puerperal fever, there was a time when everything was washed and scrubbed with great vigor. Carbolic acid was used without a stint, but these precautions have never exerted the slightest influence upon the prevention and restriction of puerperal fever."

The drift is now distinctly in the line of non-interference and restriction of vaginal examinations. The problem which we have to solve is to secure for women who are to be delivered at their homes any approximation of the security which they enjoy in well-regulated institutions; for the great lying-in hospitals, if properly managed, give an almost ideal safety to mother and child.

What are the methods adopted in the principal lying-in hospitals?

Leopold, in Dresden, employs the strictest antisepsis as to the examining finger and instruments. Thorough cleansing of the external genitals with soap and water, and $HgCl_2$, 1 to 4,000. Vaginal douches only in cases where instrumental interference is required. In former years he also used prophylactic vaginal douches. I will compare the results of the two methods.

	Without a rise of temperature.	Short rise of temperature.	Discharged up to the twelfth day.	Rise of temperature extending over several days.	Rise of temperature due to infection.	Total number of deaths.	Number of deaths as a result of infection acquired in the clinic.
Vaginal douches with $HgCl_2$ (1 to 4,000), 1,326 cases	1,101 83.3%	136 10.25%	1,227 93.28%	39 2.92%	41 3.09%	20 1.51%	6 0.44%
No vaginal douches, 1,123 cases	1,014 90.29%	63 5.61%	1,077 95.90%	23 +2.5%	15 1.33%	10 0.89%	
Difference in favor of the second method	+7.26%	−4.64%	+2.62%	−0.87%	−1.76%	−0.62%	−0.44%

	Without a rise of temperature.	Short rise of temperature.	Discharged up to the fourteenth day.	Rise of temperature extending over several days.	Rise of temperature due to infection.	Total number of deaths.	Number of deaths as a result of infection acquired in the clinic.
Vaginal douches with $HgCl_2$ (1 to 4,000), 440 cases	366 83.18%	66 10.45%	412 93.64%	7 1.58%	14 3.07%	7 1.58%	3 0.68%
No vaginal irrigation, 836 cases	759 90.7%	47 5.62%	806 96.42%	15 1.79%	9 1.7%	6 0.72%	
Difference in favor of the second method.	+7.61%	−4.83%	+2.78%	−0.21%	−2%	−0.86%	−0.68%

These investigations show superior results for the non-interfering method; but this is not all. Leopold found also ruptures of the perineum and hemorrhages from the vagina less frequent in proportion as the lubricating mucus, which nature so wisely produces, is not interfered with.

Szabo, in Buda-Pesth, pleads for discontinuing of vaginal douches in normal labor cases.[1] He proves from the material of the Buda-Pesth Maternity, that the mortality and morbidity are lower there than in the clinics in which prophylactic douches are still employed.

Pippingsköld, in Helsingfors, prescribes on entrance in the clinic a warm bath, and before an internal examination is made, a thorough cleansing of the external parts with soap and water. The hands are of course thoroughly disinfected Uterine douches he uses about once or twice a year among eight hundred labor cases. If the woman has been repeatedly examined before entering the clinic, if she has fever, or labor is unduly protracted, then he applies a speculum and, after cleansing the vagina with antiseptic cotton, administers an antiseptic douche. His mortality, all deaths included, has not exceeded 0.29 per cent. in four consecutive years.

Mermann reports five hundred cases out of the Mannheim Maternity,[2] treated without vaginal douches, and without a single death. He had no case of severe puerperal infection, and all women were discharged prior to the fourteenth day, with one exception on the eighteenth day.

Winkel, in Munich, also Olshausen and Gusserow, in Berlin, do not use vaginal douches in normal labor; I am unable to give their results in figures, but they are excellent.

[1] Centralblatt für Gynecol., No. 33.
[2] Ibid., No. 20.

I could continue to give statistics and prove that parturition without prophylactic vaginal douches is safer as with this procedure, but these figures may suffice. Now, on what reasons do the adherents of vaginal douches in all cases, base their demand?

They hold that infection is due to the micro-organisms contained in all vaginal secretions; these shall act two fold.

First, that simply through the act of labor small wounds absorb these fungi; in other words, that infection is threatened without an internal examination having been practised.

This would be contrary to all laws of nature, and out of theoretical reasons alone, it must be stamped as an impossible status. Analogous to these would be the pathogenic organisms in the oral cavity, and I believe that just as little as among millions of beings serious infection is caused by these agents, just as little will be the life or health of millions of puerperal women endangered by the presence of these microbes.

Second, that these organisms are inoculated by the aseptic finger into the abrasions which accompany every case of normal labor. This modus is possible, but as the vagina cannot and is not made sterile by vaginal douches, there is nothing gained by applying them.

Döderlein has made extensive investigations as to the character of the vaginal and cervical secretions. He said at the last Gynecological Congress in Bonn, that in the normal vaginal secretions he did not succeed in finding pathogenic bacteria, and that therefore vaginal douches were unnecessary and harmful, no matter whether internal examination has been practised or not. In pathological secretions he found in forty-six cases six times the streptococcus pyogenes. In these cases infection is possible even without an internal examination having been practised, but it is always of a mild character.

There still remains one point, which I cannot pass by unnoticed, namely, why women who have not been examined by us can yet suffer from puerperal infection. This may be due: 1. That the woman has inoculated herself with her own fingers, or that persons unknown to us have examined her. 2. Pathogenic organisms latent in old exudations, pyosalpynx, or abscesses, are through the act of labor again awakened into action. 3. Cases in which the vaginal secretions contain pathogenic microbes.

Thus I have stated the pros and the contras impartially and without prejudice. I have studied this subject with care, and the principles which guide me now in managing my obstetrical cases are the following:

First, I always try to avoid vaginal examinations, mainly relying upon abdominal palpation. He who has not examined a woman has surely not infected her. Second, I never make a vaginal examination except with aseptic fingers, and after a thorough cleansing of the external genitals. Third, I prescribe only vaginal douches in pathological cases, before and after operative interference. Fourth, I only operate with aseptic instruments.

One who carries this out conscientiously will practise obstetrics with satisfaction to himself and safety to his patient.

37 East Sixty-second Street.

New Nervous Diseases. — In the *Gazette Hebdomadaire de Médecine et de Chirurgie*, December 12, 1891, Dr. Paul Blocq has a review of a book by G. André, on the new nervous diseases, such as syringomyelia and Morvan's disease, the new types of amyotrophia, polyneuritis, astasia abasia, pseudo-chorea, neurasthenia, paramyoclonus, Thomsen's disease, acromegalia, essential paroxysmal tachycardia, etc. Neuro-pathology has made giant strides during the past ten years The volume in question Dr. Blocq thinks really fills an actual want, for the progress of late in the knowledge of nerve abnormity cannot possibly be condensed in any treatise, and merits consideration by itself.

Progress of Medical Science.

The Treatment of Ileus.—Dr. Aufrecht attributes the sudden arrest of vomiting when the stomach is distended, to a dislocation which is produced by the distended intestine forcing the œsophagus against the edge of the opening in the diaphragm through which the œsophagus passes. In stercoraceous vomiting, repeated washings of the stomach will not only act beneficially by removing the contents, but will prevent injury from absorption. Morphine, hypodermatically, is advised in all cases of ileus, and large enemata have been abandoned.—*Therapeutische Monatshefte.*

Treatment of Pertussis.—Dr. Hellet says that under the influence of ozone inhalations, lasting a quarter of an hour each day, the number of attacks diminishes, the general condition improves, and the appetite returns in a few days. Dr. Chibret claims that by sprinkling powdered iodoform over the pillow on which the child sleeps, the attacks of coughing are quickly arrested. Dr. Galvagno employs the following formula:

℞ Resorcin,
Antipyrin ..... āā gr. xv.
Acid hydrochloric ..... gtt. x.
Syr. simp. ..... ℥ j.
Aqua dest ..... ℥ iij.

of which from three to five teaspoonfuls are given daily. The average duration of cases thus treated does not exceed fifteen days. Dr. Noevius advises an infusion of thyme (100 parts to 700 parts water) to which are added 50 parts of syrup of marshmallow, and of this from a teaspoonful to a dessertspoonful is given eight or ten times a day, according to the age of the child.—*Bul. Gén. de Thérapeutique*, November, 1891.

Screw-worm Disease.—In 1883 Professor Snow called attention to some peculiar cases which had come to his notice, where larvæ of the *Lucilia macellaria*, commonly known as the screw-worm fly, were deposited in the nostrils of patients suffering from catarrh. In one case over a hundred "maggots" were taken from the nostrils, in another over three hundred were removed. This patient died, and it was found that the hyoid bone was destroyed, the nasal bones were loose, and the vertebræ entirely exposed. In the third case, which also proved fatal, the larvæ had entered the Eustachian tube. Two of these cases occurred in Kansas, and according to recent reports the disease has again made its appearance in that State, as well as in other parts of the West. Dr. Moore reports an instance in the *Kansas Medical Journal*, October, 1891. Larvæ were discharged or removed from the nostrils of a young man who worked in a stock-yard, during ten days, until the number reached 310. The most effective treatment was found to be equal parts of mercurial ointment and vaseline, melted, and while hot sprayed into the nose with an acme atomizer. Dr. Allingham puts on record in the *Occidental Medical Times*, November, 1891, still another instance, this time occurring in Bishop, Cal., in which an accumulation of maggots in the nasal cavities produced symptoms simulating meningitis. Four days before the attack the patient had been awakened by a fly entering her nose. This was removed after some effort, and found to be a large "blow fly." In this case kerosene was injected by means of a post-nasal syringe, and after five days' treatment about two hundred full-grown maggots had been secured and recovery rapidly followed. This patient, like all the rest, had for some time suffered from nasal disease, having an offensive ozæna which no doubt proved attractive to the fly. The great number of eggs deposited within a few minutes must have developed into maggots sufficiently large to cause pain within thirty six hours, and in four days they were about half an inch in length. Dr. Mitchell (*Medical News*, November 21, 1891) removed four large white worms, half an inch or more in length, from the auditory meatus of a negro in Madison, W. Va. They had caused much pain and a sanio-purulent discharge. The head of the worm was small, black, and hard.

Contribution to the Study of Internal Lesions after Burns.—Dr. Malvoz (*Annales de la Soc. Méd Chir. de Liège*, November 1, 1891), found on post-mortem in a female aged nineteen, who died six weeks after a severe burn, extensive signs of diphtheritic enteritis of the small intestine. In both kidneys there were numerous pus collections. Here and there were portions of necrotic kidney-tissue surrounded by pus. In the latter, as well as in the exudation from the intestine, were found masses of streptococci having the microscopical appearances of the streptococcus pyogenes.

Laparotomy for Intestinal Perforation in Typhoid Fever.—Dr. Van Hook (*Medical News*, November 21, 1891) concludes an article based upon a successful case of laparotomy as follows: 1. There is no rational treatment for perforation in the course of typhoid fever, except laparotomy. 2. The indication for laparotomy when perforation occurs in typhoid fever is imperative. 3. The only contra indication is a moribund condition of the patient. 4. Collapse is often at least temporarily relievable by hot peritoneal flushing. 5. The stage of the fever is not to be considered as an indication or as a contra-indication for laparotomy. 6. The severity of the typhoid fever is alone not a contra-indication. 7. Early laparotomy offers the most hope. 8. The symptoms of peritonitis should not be awaited before operating. 9. In taking charge of all typhoid fever patients, it is the physician's duty to be ready, in case of perforation, to perform laparotomy. 10. The published statistics of laparotomy for this condition are strongly in favor of operation. 11. The technique, though not complicated, demands much thoughtfulness, acquired dexterity, great rapidity, and thoroughness.

Resorcin is recommended by Dr. Menche not only in the diarrhœa of young children but also in the various forms of gastritis, a tablespoonful of a two per cent. solution being the adult dose. It has also been successfully employed in the sickness of pregnancy, sea-sickness, and peritonitis. It appears to exert an anodyne action on the gastric nerves, and in larger doses upon the central nervous system. Four-grain doses produce quiet sleep in general nervous excitability and in the insomnia of typhus and phthisis.—*Centralb. für klin. Med.*

Digitalis in Pneumonia.—Fikl has treated, during the past year, fifty nine cases of pneumonia by the administration of digitalis (Petresco's method) without a death. At first the digitalis was given in daily doses of thirty grains, or seven ounces of infusion, and this proving harmless was increased to forty-five grains daily. Morphine or chloral at night were the only other drugs employed, but alcohol was freely given. The beneficial effects were very marked, but vomiting was not infrequent, and in two cases mental effects were observed. He regards the use of digitalis as of undoubted efficacy in pneumonia.

The Fever of Chronic Rheumatism, with its evening exacerbations, Kahler thinks should be kept in mind when we have to deal with obscure febrile states. It is more or less intense and quite constant.—*Zeitsch. f. klin. Med.*

Toxic Effects of Salol.—Dr. Dérigrac (*Soc. méd. des Hôpitaux*) has observed painful phenomena referable to the stomach, diarrhœa, vertigo, weakness of the limbs, elevation of temperature, back urine (in which the per chloride of iron test showed the presence of salicylic acid), after three doses of salol of twenty centigrammes each, in a woman suffering from acute gastro-enteritis. These symptoms might have been referred in part to the disease rather than to the drug, but a subsequent admin-

istration of salol brought on the same train of derangements. In a child of twelve years a ten centigramme dose three times repeated produced the same accidents.

The Antipyrin Habit.—Dr. Combernale relates in the *Bull. méd. du Nord*, No. 12, 1891, that a servant girl suffering from polyarticular rheumatism of long duration was treated with antipyrin, which she took in dose of fifteen grains daily, and this amount was increased to thirty or forty five grains on her day of fatigue. Without this excitant she suffered from general depression, stiffness of the fingers, and swelling of the feet. For this reason she continued to take the drug regularly for four years. At the expiration of this time she showed signs of round ulcer, with pharyngeal cough, general muscular weakness, nocturnal agitation, insomnia, and amenorrhœa. The drug was left off gradually and all these symptoms progressively disappeared.

Spermato-cystitis.—In a paper on inflammation of the seminal vesicles, Dr. Lloyd (*The Lancet*, October 31, 1891) submits the following conclusions: 1. That spermato-cystitis, although seldom recognized, is not uncommon. 2. That it is in many ways analogous to salpingitis in women. 3. That it is usually secondary to urethritis. 4. That suppuration is exceptional. 5. That when suppuration occurs the pus should be liberated by incisions made from the perineum. 6. That it frequently accompanies epididymitis. 7. That it is usually diagnosed as inflammation of the prostate or neck of the bladder. 8. That diagnosis can be easily made by careful digital examination from the rectum.

A New Variety of Tropho-neurosis.—Drs. Hallopeau and Jarat report a case of tropho-neurotic skin affection, characterized by dyschromia with lichenoid eruptions surrounding the achromic plaques, which differs from any previously described disease. Their conclusions are: 1. There exists a dermatosis characterized by achromic plaques surrounded by a zone of papules and by an exaggerated pigmentation. 2. This dermatosis is very probably a cutaneous manifestation of hysteria. 3. The lichenoid papules may be of tropho-neurotic origin. 4. They are not necessarily related to pruritus. 5. Cutaneous electrization by means of faradic baths seems to be indicated in such cases.—*Revue Internationale d'Electrothérapie*, October, 1891.

New Forms of Treatment for Enuresis. — Various suggestions have recently been made as to the proper means of preventing and curing that disagreeable and often distressing condition known as eneuresis nocturna. It is more than probable that the cause of the trouble is to be sought for in widely differing directions. Thus in one case it may be an excess of carbohydrates in the food, too much meat, or a diet keeping up too great an acidity of the urine. In a second it may result from some debilitating disease through which the patient has passed, or depend upon some inherited predisposition. As local causes, Ollivier has cited abnormalities of the prepuce, phimosis, balanitis, urethritis, vulvitis and thread-worms in the rectum.

Dr. Kupke thinks it possible the incontinence is often the result of a weakness on the part of the spinal cord, which loses its power to transmit to the brain the impression of distention in the bladder. On the other hand, we must also admit that an anæsthetic condition of the sensitive nerves of the bladder can occur, by reason of which the micturition centre of the spinal cord is only feebly made aware of the need to urinate. Kupke expresses the opinion in the *Allgem. med. Central Zeitung*, that Guyon's method of electrization is most rational. This consists in introducing into the urethra, as far as the membranous portion, a metallic sound to which an electrode is attached, the other electrode being placed over the pubes or the perineum. The electric current should be quite weak at first.

Unverricht's method is to place one of the poles over the vertebral column, and the other on the symphysis pubis. In the cases which are by far the most frequent —where there is no organic affection—the author employs simultaneously faradization and interral medication, giving the fluid extract of rhus aromatica in doses of from five to fifteen drops according to age, administered twice a day in milk, and continued for three or four months. Electricity is to be given twenty or thirty times, not over five minutes at each sitting. His favorite plan is to keep the anode against the spinal column at about the lower dorsal or upper lumbar region, while the cathode is brushed over the whole bladder region.

Gaudez, in his *Thèse de Paris*, 1891, says that antipyrin gives good results in essential incontinence. He gives it in *cachets* or in Vichy water from a gramme and a half to four grammes, divided into several doses to be given at two-hour intervals, preferably at six and eight o'clock in the evening.

Koerner (*Centralblatt für klin. Med.*) says that the patient should always be examined during sleep, to see if mouth breathing denotes obstructed respiration, as he has found this a frequent cause of enuresis. Enlarged tonsils or other faulty condition in the upper respiratory passages should receive attention. Dr. William Perry Watson's plan of treatment consists in administering atropine in the following way: One drop of a solution containing one grain of atropia sulphate in an ounce of distilled water is given for every year the patient is of age, at 4 and 7 P.M. This plan was recently carried out in twelve chronic cases at the New York Infant Asylum. Slight physiological symptoms were produced in three of the little patients. After six weeks' treatment slight improvement was noted in four, seven were well at the end of the fifth month, and nine a month later; these had remained well. Five cases, including three girls, the only ones given the treatment, were but slightly improved at the end of the fifth month, but by the end of the eighth these wet their beds not oftener than twice a week.

During the tenth month there was only an occasional wetting, and the dose was now reduced one-half. At the end of a year's continuous treatment, there was no longer any wetting among the twelve, and six months after the atropia was stopped no return of enuresis had taken place.

Dr. Sänger has found good effects from the mechanical method of introducing a metallic catheter into the bladder of female children, making firm pressure backward and to the sides several times while the thumb covers the aperture of the instrument. Ten to twelve sittings are said to be usually sufficient. Such a mode of treatment, it seems to us, should not be entered upon until other milder and safer ones have been tried. In all cases we should try the effect of giving but little fluid toward evening, taking up the child several times in the first part of the night, seeing to it that the bed is a firm and rather hard one, and encouraging the child as much as possible to avoid sleeping on the back. If these fail, it might be advisable in picked cases to carry out the suggestions of a recent correspondent in *The Lancet*. His remedy is the birch-rod applied before the child is put to bed, not as a punishment, but in a true scientific spirit. Six is the regulation number of strokes, and they are to be put on where they will do the most good. After the third *séance* the cure is complete. The *rationale* of the method is that it awakens in the boy (girls should be spared the indignity) a desire to avoid wetting the bed; it draws the blood to the surface for a few hours, and thus relieves the pelvic organs; it stimulates the lumbar centre, controlling micturition through the nerves distributed to the upper gluteal region; and it prevents the patient lying on his back.

Moral: Spare the rod and spoil the bed.

Salicylic Acid is said to cause a marked diminution in virile power.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, January 23, 1892.

A SECRETARY OF PUBLIC HEALTH.

THE petition put forth by a committee of the American Medical Association, praying Congress to establish a Department of Public Health, is an able and interesting document. It ought to make some impression upon our legislators at Washington.

The petition acknowledges the work in public health done by the various existing departments of the Governments; it describes the field occupied by State medicine. It skilfully touches upon the subject of medical "schools" in the following way:

"The question," it says, "may arise with some person, whether such a department would subserve the interests of any particular school? We respectfully reply that amid all the apparent disparity in medical practice, there is one true, severe unity, and to attain this all true physicians are continually striving. There is no disputation in medical science about anatomy, physiology, pathology, chemistry, physics, or preventive medicine; the difference among doctors lies in therapeutics or the treatment of disease, and as in the past, so for all the future, practitioners will use a variety of remedies and in varying quantities, and there will be different modes of management of sick or injured people. With the advance in the way of education, the differences in treatment will gradually become more unified."

It recognizes the fact that the General Government's powers would be limited in many ways, but believes that the field would be large enough.

A Secretary of Public Health, we are assured, would represent the medical consciousness of the Nation, and "become one to whom we could look for the exploitation of measures that will direct continuous scientific and collective investigation in regard to endemic, contagious, and other diseases; the enlightenment of the people in sanitary ways of living; the dissemination of information respecting the most favorable places of residence for those afflicted with such chronic diseases as asthma, rheumatism, neuralgia, and consumption; the examination of food and drinks; medicinal springs; the collection and tabulation of vital statistics at large and in various localities, such as the congested areas of our great cities and among various races. He would be able to co-operate with State Boards of Health, the Signal Service, the medical departments of the Army, Navy, and Marine Service, unify and utilize their work, and thus make the Department of Public Health the repository of the most important facts that concern the comfort of the people; and his duties will grow broader and stronger in adaptability to public needs."

A Secretary of Public Health, to put the matter in few words, could, as an officer of the National Government, deal executively only with the subject of national quarantine. All his other functions would have to be those of an adviser, teacher, investigator, and co-operator. But such an adviser and investigator, with the power and dignity of the Government behind him, would wield an enormous influence for good. The establishment of such an office would at once attract such attention to hygiene, and give such prominence to its work, that advances in the education of the people and the promotion of sanitary reform would take place much more rapidly. Very few people yet understand that there is no reason why such things as measles, scarlet fever, yellow fever, diphtheria, or cholera should exist, and that in time civilized communities will stamp them out.

PARTURITION IN HYPNOTIC SLEEP.

SINCE Eve first heard that awful sentence, "In sorrow thou shalt bring forth children," pronounced from the highest tribunal upon her and her sisters, science has at times seemed determined to antagonize the biblical precept that woman must thus have her sorrows increased, and some advance has been made toward a mitigation of the severity of the punishment.

The discovery of chloroform and the application of its analgesic powers to the parturient state has made it quite possible for the child to pass beneath the pelvic arch, or, as Dr. Holmes poetically puts it, "beneath that triumphal arch through which every candidate for immortality has to pass," without causing more pain to the mother than he is conscious of experiencing himself.

Dr. Oui, of Bordeaux, is as positive as his very affirmative name would make us believe he would be on any subject, that hypnotism will produce the same results in certain cases. In the *Annales de Gynécologie* for November, 1891, this gentleman, who is the *chef* of the obstetrical clinic, relates an interesting observation in the case of a primipara with hysterical tendencies, who had been repeatedly hypnotized for the cure of hysterical coxalgia. When in childbirth, and at the moment of complete dilatation, the head resting on the perineum, and the pains being so severe as to cause the patient to cry out lustily, hypnotism was induced by closing the lids and pressing upon the globes of the eye. So long as the pressure was maintained the patient uttered no sound and the face remained absolutely calm. She obeyed, however, all instructions, bearing down when told to, and ceasing all effort on command with equal docility. A good-sized child was born and presented to the now awakened and astonished mother, who declared that she had suffered not the slightest pain.

Here, then, we have a ready method. No longer is there any need of dangerous anæsthetics. With one hand you take away your patient's senses and with the other the child. Now, for the first time in the history of medicine, is a man justified in printing beneath his name, "Children extracted without pain, fresh hypnotism every

day." There is only one drawback: the patient should be somewhat hysterically inclined, and hysteria is a condition not readily induced, nor would it be wise to induce it if we could; so, for the present at least, the method must have a limited application. Besides this, many investigators have shown that it is during the pains of labor, and especially of the expulsive effort, that hypnotism is produced with the greatest difficulty, though Pritzl is said to have succeeded in one other case.

Dr. Oui regards the condition in his case as closely allied to that of lethargy, with muscular relaxation and analgesia—the latter due to the hypnotic state, and not to suggestion.

PHAGOCYTES AND LONDON POLICEMEN.

In the Croonian lectures recently delivered by J. Burdon Sanderson, before the Royal College of Physicians, on "The Progress of Discovery Relating to the Origin and Nature of Infectious Diseases," he draws attention to the difficulty of supposing that in the spread of traumatic erysipelas the invading myriads of streptococci can be effectually opposed by the leucocytes which follow in their rear, and at the same time to a very reprehensible practice on the part of the London Bobby. He says: "A similar difficulty exists as regards the more specific infections. If phagocytes are to be looked upon as policemen, whose business it is to watch over the safety of the organism, they ought to present themselves in force wherever and whenever there is danger. Now, Metschnikoff's own observations, confirmed as well by his supporters as by his opponents, show that that is precisely what does not happen; that is, that although it is perfectly true that leucocytes take part in the local reaction to which the entrance into the organism of many pathogenic microbes give rise (they are like policemen in this respect), they neither appear at the place nor at the time that they are wanted. For if we compare the reaction which a mitigated culture produces in the subcutaneous tissue of a healthy animal with that which is evoked by a virulent one, we find that the main point of difference is that whereas in the former case, where there is no danger, our policemen assemble in force, they are either entirely absent or appear in scanty numbers where danger is imminent."

Morbid somnolence has been charged against our own guardians of the peace, but they have never yet in public been compared to phagocytes.

Many a man has resorted to the night force of the constabulary as a cure for inveterate insomnia, but once refreshed by perambulatory sleep he is ready for any emergency.

AN EXPERIMENT IN HEREDITY.

In the preface of a new book, Alexandre Dumas *fils* suggests a method at once practical and scientific of solving the vexed question of heredity. Instead of executing a condemned criminal, which really proves nothing, why not utilize him and make him prove something? Why not banish the burglar, cut throat, or other malefactor, to some penal colony and there secure for his constant companion a depraved woman fully his equal in degradation? Why not see what such a union could produce in the way of offspring? Or rather, why not discover what could be made of the product of such an alliance, by complete change of environment, care, education, by the same attention as is bestowed upon well-born children? Removed at birth from evil influences, brought up in ignorance of its origin, and in a clean and healthful locality, where vice and crime are practically unknown to the childish mind, Dumas opines that it would be interesting and safe to leave the little one to nature and empiricism. This plan would be an instance of superior or human selection, the same human selection that, through various processes of care and cultivation, has given to the world (from crude prototypes) the rose, the apple, and man's trusty friend, the dog. Heredity, as generally understood, is purely theoretical. If the foregoing experiment in heredity should chance to result in a bright, intelligent, and upright citizen, useful and well conducted, what a glorious discovery this would be for the world, what a step in advance, what a practical refutation of original sin and the depressing fatalism of science! The idea is certainly original, and as yet untried with definite intent, for the chance children of such painfully equal unions have not had their histories recorded. For the weak environment is more than heredity. They are weak because this is so. The strong overcome the limitations of environment, they alter it to fit their measure. Children of energetic criminals might be supposed to thrive in an orderly way when transplanted and the right direction given to their activities. The only fatal thing is weakness, is stupidity. The gods themselves are powerless before it. The live dog always excels the dead lion; and the wicked man, even before he turns from his wickedness, is a more hopeful subject than the weak one.

THE GUAIACOL TREATMENT OF TUBERCULOSIS.

While we are waiting for the discovery of a specific remedy for tuberculosis that is not more dangerous than the disease itself, we may just as well look around us and see what we can do with the remedies already in our possession. There is perhaps no disease, unless it be diphtheria, for which there are so many favorite methods of treatment, and there is no disease, not excepting diphtheria, where as much disappointment is experienced in the employment of these special methods by others than their originators.

That pulmonary tuberculosis is curable, or rather that it does not always progress to a fatal termination, has been shown again and again in autopsies where the lungs present unmistakable evidences of having once been the seat of tuberculous lesions. The bacilli have obtained a lodgement at some period and have begun their ravages, but the organism, aided perhaps by hygienic or medicinal remedies, has proved itself strong enough to destroy the micro organisms, and repair as far as possible the injury done by them. In this fact the therapeutist finds encouragement for renewed effort, and upon it he rests his hopes of ultimately triumphing over the scourge of mankind.

Among the many so-called specific remedies that have found favor in the treatment of the disease, creasote is perhaps the most frequently employed, and it has seemed

in numerous instances to have really been of considerable service. One of the first to employ this drug experimentally was Dr. Max Schüller, who as long ago as 1878 began to use it in experiments on animals. He tried a number of remedies of this class, but finally settled upon guaiacol, which is the chief ingredient of creasote, as the substance which gave him the best results. After he had made a thorough and satisfactory trial of the remedy in animals, he began to employ it in the treatment of various forms of tuberculosis in man, and has recently published his results in the form of a monograph,[1] in which he describes his method and gives in detail a list of various cases of tuberculosis of the lungs, skin, bones, and joints treated by him up to the present time.

The cases are comparatively few in number owing to the fact that he had no clinic to draw upon, but was obliged to seek his material in his own practice. One advantage of this is, however, that he had to wait several years to get a sufficient number of cases, and in consequence his earlier cases were under observation for a considerable period, giving him the opportunity of seeing that the cure was a permanent one, and not a mere temporary improvement. We cannot here refer to his cases in detail, but will give simply the results. He tabulates 100 cases of surgical tuberculosis in which guaiacol was given, and of these there were 70 cured and 16 improved, 10 passed from under observation, and 4 died. In about fifty per cent. surgical measures, such as resection, iodoform injection, etc., were resorted to, in the others the guaiacol treatment alone was employed. He gave the remedy preferably pure, in doses of two to five drops in milk, bouillon, wine, etc. In other cases it was given according to the following formula:

℞. Guaiacol..... ℥ j.
Alcohol,
Aq. menth. pip.....āā ℥ v.
Ol. morrhuæ..... ℥ jss.
M. Sig. . A tablespoonful in wine, beer, milk, or water, four or five times a day. Shake the bottle thoroughly before using.

Dr. Schüller insists upon the persevering and long-continued use of the remedy in moderately small doses, and does not think large single doses are of any special therapeutic value. Guaiacol has a very disagreeable odor and taste, yet it seldom disorders the stomach and patients grow accustomed to it, so that its use becomes less and less disagreeable, until finally it is well tolerated even if not enjoyed. An improvement was noted in most of the cases in a short time, but the remedy was continued for a long period until a cure was obtained, or until it became evident that the disease was too far advanced to hope for recovery. Almost all of the cases were of surgical tuberculosis, but in many of them there was also disease of the apex, and in these the good effects of the remedy in pulmonary, as well as in articular, tuberculosis, were satisfactorily demonstrated.

Other writers have employed guaiacol or creasote in the treatment of pulmonary tuberculosis, and many of them have reported results nearly, if not quite, as satisfactory as those obtained by Schüller. They do not prove that we have in these drugs a specific for the disease, but they do show that the remedy may be of service, and may be a cure in incipient cases where, as an English writer has recently expressed it, we have pulmonary tuberculosis but not yet phthisis.

[1] Eine neue Behandlungsmethode der Tuberculose, besonders der chirurgischen Tuberculosen, von Professor Max Schüller. Wiesbaden: J. F. Bergmann, 1891.

LEPROSY AND SEGREGATION.

The Pennsylvania State Board of Health has just caused to be circulated among physicians who would be likely to know something about leprosy in the United States, a series of questions bearing upon its prevalence, contagiousness, and the best means to rid the country of it. It is not stated what object the Board has in view, but from the fact that the Philadelphia Board of Health is said to have sent a memorial to Congress in favor of the establishment of stations for lepers in various parts of the country under Federal control, it is to be presumed that the State Board intends lending its aid in the same direction. If this most desirable end can be accomplished by combined effort, every city and State board in the country should join in the work. There are not many lepers in New York, but there are too many. It is said that the Chinaman Ong Moy, or Tsang Ding, recently arrested by the Board of Health and sent to Charity Hospital, is rapidly developing into a case of elephantiasis of the white variety. He doesn't want to stay, the other patients want him to go, the doctors don't care to have him remain, the Commissioners are not anxious to continue their hospitality, and the Board of Health would willingly remove him if they knew how or where to get rid of him.

Now, if one innocent "Chinee" can cause so much trouble, what will happen when the city is called upon, as it some day may be, to provide for a number. Besnier has just startled the Parisians by announcing that there are at least one hundred lepers within the walls of their gay capital. Is it not possible that New York may some day be equally surprised?

We have leprosy all about us, and in spite of quarantine regulations it enters the country. In Jamaica alone the estimated leper population is 450, or one leper to every 1,380 of the residents of the island, and Jamaica is not far off.

New Orleans has a large and apparently increasing native leper population, and if anything is ever to be done to stamp out the disease in the United States it ought to be done now.

Dr. Washington F. Peck, who died a few weeks ago in Davenport, Ia., was born in Wayne County, in this State, in 1842. He served as surgeon in the army during the civil war, and at its close settled in Davenport. He founded the Medical Department of the Iowa State University in 1869, and at the time of his death was Professor of Surgery and Dean of the Medical Faculty. He was also surgeon-in-chief of the Chicago, Rock Island & Pacific Railroad.

To Reduce the Evils of Prostitution.—An association has recently been founded at Buda Pesth, the object of which is to combat the evils of prostitution, to rescue its victims, and to establish and maintain a free dispensary for the treatment of poor patients suffering from venereal disease.

News of the Week.

The Death of Dr. Daniel Ayres, of Brooklyn.—Dr. Daniel Ayres, one of the leading physicians in Brooklyn, died January 18th, at 91 Lafayette Avenue, in his seventy-second year. He was born in Jamaica, L. I. He studied medicine with Dr. David M. Reese and Dr. Valentine Mott, and received his degree at the New York University in July, 1844. He served for a short time on the medical staff at Bellevue Hospital and on Blackwell's Island. In 1845 he went to practise in Brooklyn. Some of his surgical operations attracted wide-spread notice, and he became the physician of many wealthy families. He was attached to the Brooklyn Hospital as far back as 1846, and he remained an ardent supporter of the institution to the close of his life. He was one of the founders of the Long Island College Hospital, and was its first professor of surgery. He was professor emeritus of chemical surgery in the hospital at the time of his death. In 1856, the degree of LL.D. was conferred on him by Wesleyan University at Middletown, Conn., to which he had made bequests amounting to $275.000. He was a graduate of Princeton. He contributed $10,000 for the support of the Hoagland Laboratory, an annex to the Long Island College Hospital. His other contributions to medical and other institutions would foot up, it is said, more than $200,000. His widow and two sons, Dr. Morgan Wilcox Ayres and Dr. H. Messenger Ayres, survive him.

Medico-legal Troubles in Buffalo.—The suit of Dr. Rachel Kemball *vs.* Dr. Charles Cary, Professor of Materia Medica and Therapeutics in the University of Buffalo, ended, December 21st, in a disagreement of the jury. In August, 1888, the plaintiff was struck by a bicycle, sustaining an injury to the right hip. She has since walked mainly with the help of a crutch, claiming that the neck of the femur is fractured, and charging Dr. Cary with malpractice. Professor Roswell Park swore that he had attended her four days, and had carefully examined the hip twice, without finding any signs of fracture, before he met Dr. Cary at the plaintiff's house, and that he believed Dr. Cary had not attended the patient before that time. Professor Stockton corroborated this evidence. The plaintiff was sent to the insane asylum by Drs. Park and Cary, on account of marked maniacal symptoms. After her discharge in about two weeks, Dr. Cary attended her. The defence, adopted and supported by the testimony of Dr. Park and Dr. Tremaine (U. S. A. surgeon, retired), is the theory that the present condition of the hip was probably one of chronic arthritis. The prosecution brought forward other testimony to prove that there was an ununited fracture. Many physicians and students attended the trial. From a medical standpoint the evidence was in favor of the defendant. The plaintiff has indulged in considerable litigation with reference to her injury, having in 1888 sued a bicyclist, who proved an alibi, and having recently begun suit against Dr. Park for false commitment to the asylum.—*Cor. Weekly Medical Review.*

A New Hospital Feature for Preventing the Spread of Infectious Diseases.—The *Medical Press and Circular*, November 4th, has a description of a new hospital at Berlin, called the "Emperor and Empress Frederick Hospital." The pavilion for diphtherical patients has a peculiar arrangement which is designed to imprison the contagium of that disease, whether brought there or generated there. This pavilion is entered by what is known as the "schleuse," or sluice. No person is allowed to pass directly into the ward from the outside world, but must pass from the porter's room into the "schleuse." There the visitor must take a bath and change his clothes; the same process must be gone through with on leaving the pavilion.

New Journal.—The *Doctor's Weekly*, edited by Dr. F. King, has recently appeared and promised to be good.

Death of Mr. John Wood.—The death is announced of Mr. John Wood, F.R.S., for many years Professor of Surgery in King's College, and well known to many generations of King's College students of an early date as a teacher of anatomy.

The Surplus of the Amount collected on the occasion of Professor Virchow's seventieth birthday, after defraying the expenses originally contemplated, is 20,000 marks, which sum has been added to the "Rudolf Virchow Fund," for scientific investigation. This fund now amounts to 97,000 marks.

A Laboratory of Physiological Psychology has just been opened in the Sorbonne, at Paris. Persons wishing to make original investigations, or to acquaint themselves with the methods of research at present in use in the domain of physiological psychology, should apply to the director, Dr. A. Binet.

International Dermatological Congress.—The Second International Congress of Dermatology will be held at Vienna, from September 5 to 10, 1892. Professor Kaposi is president of the Organizing Committee. The general secretary is Dr. G. Riehl.

Poisoned Wall-paper a Humbug.— Professor Chandler's discourse at the Academy, at its last anniversary, was a sharp arraignment of Boston doctors. It is not often that one of the spokes turns on the hub in this way. It is well for the peace between the two cities that the castigation did not come from a real M.D. For while Professor Chandler is a member of a medical faculty, and once received the honorary degree of M.D., he seems never to have used it, and to always speak of himself as a layman when among doctors. He is enough of a doctor to weigh medical evidence very accurately, and to know the true value of subjective symptoms. Dr. Chandler says that the arsenical poisoning idea in Boston is a fad, and with the late Dr. John C. Dalton, himself a native of Massachusetts, he believes that the whole idea of anybody's being poisoned from wall-paper is a humbug. —*The Post Graduate.*

A New Heart Tonic of especial value in nervous disturbances of the heart is tincture of coronilla varia, in doses of from five to fifteen drops.

The Therapeutic Gazette begins the new year under the editorial management of Hobart Amory Hare, M.D., George E. de Schweinitz, M.D., and Edward Martin, M.D.

A New Method of Securing Dilatation of the Os, in protracted labor, has been discovered by Dr. J. F. Bird,

of Philadelphia. It consists in making the patient smoke a pipe until nausea is produced. When carried beyond this point it will probably produce dilatation of the mouth, with vomiting.

The Test of a Medical College in Good Standing.—The Oregon Supreme Court has reversed the finding of the Circuit Court in the case of Barmore *vs.* the State Board of Examiners. Barmore had been refused a certificate by the board upon the ground that the Oregon State Board had adopted a rule which defined "medical institution in good standing," as used in the act, to mean "only those institutions which required three regular courses or sessions of six months each, extending over a period of three years' time," and that the school of plaintiff did not, when he graduated, have such a three years' course. The action of the State Board is sustained.

An Army Medical Board will be in session in Chicago, Ill., during February, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies Persons desiring to present themselves for examination by the Board will make application to the Secretary of War for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they are graduated, and a record of service in hospital, if any, from the authorities thereof.

Onabain is said by Dr. A. Rixa (*Therapeutic Gazette*) to be a more powerful local anæsthetic than cocaine.

The Dispensary Abuse.—The anxiety of the medical press of New York City over what is termed the "Dispensary Abuse" is amusing, especially to an outsider. It reminds us very forcibly of the old story about the man who found the frozen serpent and warmed it back to life by cuddling it in his bosom, when it promptly stung him for his pains. The medical profession of New York took the afflicted pauper in and is now being "taken in" as a return.—*Medical Fortnightly*, St. Louis.

Have We a Bogus College in our Midst? asks an esteemed contemporary. Heaven forbid! It's bad enough to have gall-stones, and other such ordinary bowel irritants, without introducing a whole college, and a bogus one at that.

The City Hospital Medical Society, formed of alumni of the St. Louis City Hospital, was recently organized in that city. It has no president, but the presiding officer is chosen at each meeting to serve for that evening only.

The Doctor and the Priest.—The omission of a "not" in the editorial item under this heading in the issue of January 16th, changed entirely the meaning of a sentence. As printed, the sentence read, "we believe any true physician . . . . would do so, and would oppose any obstacle to the free intercourse of priest and penitent." It should have been, "and would *not* oppose," etc.

Scheyne-Stock Respiration is the way a writer in *Le Progrès Médical* spells it.

Dr. Dimitrie Sergiu, of Bucharest, widely known as a writer on diseases of children, died in that city on November 9th last.

Shall Clergymen Pay the Physician for Services?—This question has come up for discussion, based upon the bill of a Brooklyn physician made against the estate of a Catholic priest for services rendered. The heirs protested on the ground that it was usual for physicians to make no charges under the circumstances. There is no reason why this should be so, however, as was very properly stated by a priest in voluntarily answering the question in a letter to one of the newspapers. We entirely agree with the latter assertion and that, save in a very few exceptional cases, charges should always be made. The physician pays the priest for the marriage ceremony, for christening, and his heirs are expected to be ready with an honorarium when mass is said at the funeral of the doctor, when his many deeds of charity are over. Nor does the physician enjoy a free pew in the church of his choice on the score of helping the deserving poor of the congregation. As a mere matter of advertisement for practice it seldom if ever pays, as the clergyman in many cases chooses a physician for himself, but for policy sake does not care to recommend one doctor more than another for members of his flock. But more than all, the services to the priest or minister are valued in proportion to the amount actually paid for them.

Singular Death-rate in the Academy of Medicine of Paris.—Of the one hundred resident members of the Academy of Medicine of Paris, five, or one-twentieth of the whole, died between November 15 and December 30, 1889. The deaths occurred in the following order: Roger, ex-president of the Academy, Féréol, Annual Secretary, Barthez Moutard-Martin, former president, and Richet (père), former president. Féréol was the youngest, being sixty-two, the ages of the others being between seventy two and eighty-four. There are however no young men in the Academy, most of the members being over sixty.

New York Pathological Society.—The following officers were elected for the ensuing year. *President*, Dr. H. P. Loomis; *Vice-President*, Dr. J. C. Thacher; *Secretary*, Dr. O. C. Ludlow; *Treasurer*, Dr. J. H. Hinton; *Editor*, Dr. G. C. Freeborn; *Committee on Admission and Ethics*, Drs. R. H. Sayre, H. D. Stearns, J. C. Ely, S. T. Armstrong.

Regulating Fees.—The physicians of Passaic, N. J., have formed an association for mutual encouragement, and have adopted a fee-bill, according to which they will charge $1.50 for day calls, and $3 for night visits—not an exorbitant charge certainly.

The Chicago Medical Society, now numbering about seven hundred and fifty members, has at last found a place where it may sit in peace and the fulness of its wisdom, at least until the buds begin to break and the spring birds come again. A hall of good proportions has been leased for a few months, and the charity of a large hotel goes unsatisfied (?). Dr. Church has ably called the attention of the profession to the need of a "medical home," so to speak, a place of general rendezvous for the medical societies and the whole profession, resident and transient, but as yet no fruit has appeared to his sowing.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, December 15, 1891.

FRANCIS DELAFIELD, M D., CHAIRMAN.

A Study of the Processes which Result in the Arrest or Cure of Phthisis, was the title of a paper read by DR. H. P. LOOMIS. (See p. 29.)

DR. J. WEST ROOSEVELT said that from a clinical stand point it was very important to remember that healed phthisis is not (clinically speaking) phthisis. It was not the kind of phthisis which came under our notice in practice. Doubtless we all saw cases of phthisis which we did not diagnosticate, and there was no reason why we should do so. In incipient phthisis, it was well known how very difficult it often was to make a diagnosis, and there were in all probability many cases of phthisis which recovered without coming under the physician's care at all.

Dr. Loomis had referred to the great frequency with which pleuritic adhesions were found in the cases examined by him after death (thirty six per cent.). Clinically, nothing like this percentage was noticed. He hoped that the doctor would succeed in throwing some light on the lymphatics of the lungs, as hitherto it had seemed utterly hopeless to try to understand the pulmonary lymph-currents. He did not understand why Dr. Loomis held that the pleuritic fibrous adhesions should be considered as secondary to phthisis. It seemed to him that they were merely a part of the phthisical process.

The Chairman, DR. DELAFIELD, said that in his paper Dr. Loomis had given an exact and complete description of the conditions which anyone accustomed to making autopsies constantly meets with. For some time he had believed that the reason for the apparent discrepancies which so often exist between the clinical history and the post-mortem appearances was this, that we have got so much in the habit of regarding all tuberculous inflammations as very serious, if not absolutely fatal. Whereas, it was unquestionably true that a tuberculous inflammation, if it occupied only a small area in the body, could be a very little matter; provided it remained confined to a small part. He was convinced that a large number of persons have a very small tubercular inflammation of a small part of the lung which never even makes them sick. The inflammation runs its course, and they recover from it; afterward, when they die from some other cause, the evidences of the previous tuberculous trouble are found at the autopsy. When larger areas were involved the inflammation might run its course also, but so much of the lung would have been implicated that such persons could hardly be called very healthy. There would be no longer an active inflammatory process, but the lung would always remain more or less damaged.

As regards the healing of tuberculous lungs by the formation of new connective tissue, this was a question of very great importance. The presence in the lung of tubercle bacilli was itself of no consequence. But the bacilli were of consequence when they had excited an inflammatory process. This process either went on to death or underwent healing. These things might happen: 1. We may have a simple exudative inflammation, with the formation of its characteristic products; and all this exudation may be absorbed and disappear from the lung. 2. We may have the formation of new connective tissue; and such tissue has very little tendency to disappear. On the other hand, it has a tendency to become changed into a denser connective tissue.

This did not seem to him to be a barrier to further tuberculous trouble, as Dr. Loomis had contended. The only thing that could happen was that it could be changed to new connective tissue, and it was not, in his opinion, a source of protection against tuberculosis. The paper was a genuine "dead-house paper," and it contained an accurate description of a very real thing. The only question was as to how that real thing was to be interpreted.

Exact Records of Physical Signs, was the title of a paper read by DR. CHARLES E. QUIMBY.

DR. FRANK W. JACKSON said that he could not agree with the author of the paper, as to the relative importance of pitch. In determining the variations in physical signs he did not think that the condition present was best demonstrated by the pitch; but that the quality of the sound heard was of just as much more importance than the pitch, than auscultation was of greater value than percussion. Quality was, in his opinion, the important element. In an orchestra, all the instruments were tuned to the same pitch, but it was the individual quality of each instrument which was its distinguishing characteristic. He did not think that the essential differences in sounds heard are recognized by the pitch. For instance, abdominal tympanites had a high pitch. We might get the same in percussing over the lungs. Yet the most inexperienced examiner would have no difficulty in distinguishing between the two sounds, which were very different in character. It was, therefore, the quality by which each was recognized. Dr. Quimby had stated that in pulmonary emphysema Dr. A. A. Smith described the note as high in pitch, because he heard the sound at the chest-wall, while Dr. Loomis described it as low in pitch, because he heard only the lung sound beneath. It did not seem clear why the examiner should not differentiate between these two notes.

DR. QUIMBY said that he had evidently failed to make himself understood. The matter was simply this: We were all the time talking about pitch, and what he suggested was that we should write the pitch down, so that there would be some exactness in our records. In regard to emphysematous percussion, there were two distinct notes, and they could be readily differentiated. There was, first, the surface note, and second, the resonant note from the amount of air contained in the whole chest-cavity. Each note had its peculiar pitch, and this could be readily illustrated by striking a kettle-drum on the wood. In the paper nothing was said about quality, or other characteristics of physical signs.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 28, 1891.

GEORGE H. FOX, M D., PRESIDENT, IN THE CHAIR.

The Therapeutic Results of Direct Electrization of the Stomach.—DR. MAX EINHORN referred, in the first part of a paper bearing this title, to one previously published in the MEDICAL RECORD, describing the method which he employed in electricizing the stomach.

DR. A. D. ROCKWELL said that during some months past he had treated several cases by direct electrization of the stomach in the manner described by the author, yet thus far he could not say that it had shown much advantage over the external method. It could hardly be called direct electrization, since the electrode did not come in direct contact with the mucous membrane of the stomach, but exerted its influence through the fluids. More recently he had tried, with some satisfaction, the bipolar method, or that by introducing both electrodes into the stomach. It required greater caution than the other method, since the same current produced a much greater effect.

Clinical Remarks on Acute Pulmonary Œdema.—The discussion on the two papers read at the last meeting of the Society was continued. DR. H. N. HEINEMAN first spoke upon Dr. A. A. Smith's paper on acute pulmonary œdema, stating that he did not think all the different causes of all the different varieties of acute pulmonary

œdema had yet been established. A vaso-motor neurosis would account for only a part of the cases, and he must disagree with the author if it were held that the heart was not at fault in some. Without going into the particulars regarding treatment, he might state in general that it must differ according to the cause.

Dr. W. H. Porter thought disturbance of innervation relating to the respiratory act, and consequent deficiency in aspiration force which was so important a factor in clearing the lymphatics, had much to do with acute pulmonary œdema. Where this was a cause, dry-cups, quickly and forcibly applied, would do good by their reflex influence. He agreed with Dr. Heineman, that no one mode of treatment could be relied upon for all cases.

Dr. A. Jacobi said the class of cases of acute pulmonary œdema which had come under his observation must have been of a more threatening nature than those referred to by Dr. Smith, who had spoken of repeating doses of certain medicines only once in two hours. Many of these patients might die within two hours, some within fifteen minutes, and, therefore, something very effective had to be employed. If strychnia were to be given in doses of one-fiftieth of a grain he would certainly agree with Dr. Kinnicutt, and repeat it in fifteen or twenty minutes instead of waiting two hours. In some cases of myelitis, polio-myelitis, and one of hemiplegia, he had given as much as one-fifth of a grain of strychnia hypodermically without any signs of poisoning.

Regarding digitalis, he believed the author had objected to it in pulmonary œdema because it acted on the arteries, and propelled the blood into the veins. This objection seemed to him without weight, for it was by driving the blood from the arteries into the veins that we also caused it to pass from the veins into the arteries. In other words, the circulation was kept moving, which was desirable. But to produce any effect it must be given in large doses, say ten drops of the fluid extract. Where there was a strong bounding pulse, venesection might do good Pilocarpin might be useful. And if one could wait two hours for the effect of a drug in these cases, as the author would seem to think, he saw no reason why a strong cathartic might not prove useful. The hot pack might be beneficial in bringing on diaphoresis. Besides heart-stimulants and vaso-motor stimulants already mentioned, he spoke favorably of the effect of caffein used subcutaneously, say in the form of the salicylate. He did not doubt but what acute pulmonary œdema was due, at least sometimes, to a vaso motor neurosis.

Perityphlitic Abscess.—The discussion on Dr. McBurney's paper on "The So-called Simple Incision in Perityphlitic Abscess," read at the previous meeting, was continued.

Dr. A. Jacobi would substitute the term timely operation for that of early operation, for the simple reason that, according to surgeons themselves, what would be considered a proper time to operate in one case would be too late in another. By speaking of the need of an early operation, some surgeons less experienced than others might be misled to interfere early, when one more experienced would very properly wait a day or days longer, and give the patient a better chance. Then there were many cases, which in the beginning could not be diagnosticated exactly, which would get well without interference. The combined judgment of physician and surgeon was called for.

Dr. H. N. Heineman mentioned a case in Roosevelt Hospital, in 1874, that of a woman who had a perityphlitic abscess point posteriorly, yet the entire staff failed to recognize its true origin until it was discovered at the autopsy, three or four years later. He agreed with Dr. Jacobi that the word timely was better than early or late, as expressing the time when an operation should be performed in perityphlitic abscess, for the reason that, as Dr. Delafield has shown in the case of pneumonia, the rapidity of the pathological changes varied in different cases.

Dr. W. Gill Wylie agreed with Dr. McBurney, that an operation should be performed early where it could be determined that an abscess had probably formed. Where one waited and made the so-called simple incision, failing to go further and break up, as might be called for, adhesions or remove a slough, there was danger of subsequent intestinal obstruction. If a slough were to form, or rupture take place into the free cavity while waiting until a simple incision could be made, death would almost surely result.

Dr. McBurney approved of the use of the terms timely and untimely, but they were not necessarily opposed to those of early and late. He did not agree with Dr. Wylie, that signs of pus-formation should decide the operation. The appendix might be gangrenous without pus-formation; the patient might be gravely ill and no pus be found. He would be guided by the judgment of both physician and surgeon, and operate where the patient was evidently seriously ill, rather than be controlled by the evidence of the presence of pus. He hoped the practice of aspiration to determine the presence of pus would never be renewed.

Dr. Wylie thought he had been misunderstood. He thought we should always operate where there was pus. But of course there might be other indications for opening the abdomen. He thought the apparent seriousness of the patient's condition could not alone be taken as a guide, for he had sometimes found pus when the patient's condition in general seemed rather favorable.

Ophthalmologist's Antiseptic Cap.—Dr. G. E. Abbott thought that ophthalmologists were not quite as exacting in antisepsis or asepsis as were gynecologists, else they would insist on having the field of operation thoroughly shut off from the surrounding parts which did not permit of thorough disinfection. He, therefore, presented them with a thin rubber cap to be drawn over the patient's head, covering the hair.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 21, 1891.

The President, S. B. W. McLeod, M.D., in the Chair.

The Non-contagiousness of Leprosy.—Dr. L. Duncan Bulkley read a paper with this title. Up to fifty years ago, at least, one presenting a paper on the subject of the non contagiousness of leprosy would have had no listeners, so widespread was the belief in the contagiousness of the disease. Even to day, among many people the presence of a patient with leprosy would excite more fear of contagion than a case of diphtheria. This view seemed to prevail not alone among the laity, but to some extent also among physicians. It was the author's purpose to present such facts as had come under his observation bearing on the subject of the contagiousness or non-contagiousness of leprosy.

To account for the widespread belief in the contagiousness of the disease he referred to the biblical statements concerning it, its wide diffusion throughout the world, and failure heretofore to account for the spread of the disease in any other manner.

First, with regard to the biblical accounts, he said that no conclusions could be based regarding the contagiousness of leprosy thereon, for it was certain that at least five or six different types of cutaneous affections were included under this term, some of which were highly contagious and others were not. Nor could more reliance be placed on the statements contained in early literature. Further, with regard to its widespread diffusion, it might be said that malaria was quite as widespread, and yet was not contagious; the same was true of cancer, sarcoma, etc It might be stated without hesitation that the spread of leprosy did not in any part of the world correspond in manner with the spread of any of the contagious diseases; where the

disease was not endemic it showed no special tendency to spread. For instance, English observers were positive that not a single case of communication of the disease had ever taken place there. In our own country leprosy was not very uncommon; every hospital in this State probably had had one or more cases under treatment; he had personally seen several; the diseased parts had been freely handled by both physicians and inmates of the hospitals, yet in no case could it be asserted that contagion had arisen. Evidence of this character of the non-contagiousness of leprosy could be obtained in all parts of the world.

Regarding the well-known case of Father Damian, he quoted the opinion of Dr. Rigg, of Trinidad, now chairman of the English commission to investigate the subject of leprosy in India, to the effect that, to his mind, the contagious origin of the disease in this case was far from conclusive. He may have imbibed the leprosy germ in water, food, or air. A sister had lived in the same leprous colony since 1858, and was still active and in good health. Dr. Rigg himself had never come across a case due to contagion.

It was true that cases had been reported here and there where persons were said to have contracted leprosy by contagion, but so far as the author had been able to ascertain, they were not supported by direct facts. One case had been reported in which an attempt had been made to inoculate the person with leprosy, and it was said to have proven successful, but later it had been found that this person had a cousin and an uncle afflicted with leprosy, so that heredity may have played the part.

The absence of any satisfactory explanation for the spread of the disease except by contagion, had also favored the theory that it was transferred from one person to another. But it might be remarked that not many years ago scurvy was considered contagious, owing to its rapid spread among all on board a vessel. But now this disease was known to be due to absence of vegetable food. Trichinosis was also once supposed to be contagious, but at present was well known to be due to a parasite.

The author here referred to the germ theory, and stated that the bacillus of leprosy had been found in patients in all parts of the world. Where it had apparently been absent there probably had been some failure in the technique. Race, climate, soil, had apparently no relation to the disease. Hygiene seemed also unable to account for its causation in the first place. Heredity was at one time supposed to be the general way in which the disease arose, yet the number of instances where children born of leprous parents had escaped was very considerable.

Coming to the question of diet, it would seem, as Jonathan Hutchinson had shown, that only one article of food was used the world over, namely, fish. The argument which this well known author had advanced in favor of the fish theory was very strong. Leprosy appeared in all parts of the world indifferently, yet the largest number of cases were to be seen on the islands of the ocean and along the seacoast. Further, it was believed to exist more among that class of people who ate their fish nearly raw, in a partly decomposed state, or preserved. It was not impossible, too, that bacteriology would prove the development of the germ of leprosy in the flesh of fish under certain conditions. The author thought, at any rate, that this offered a more satisfactory explanation of the development of the disease than the theory of contagion. While, of course, it was not impossible for the disease, if it were due to a germ, to rise by contagion, yet the degree of contagiousness must be extremely small, and could not apply in certain instances which had come under his observation. He had seen two or more patients in whom leprosy had developed in this country, and who had never come in contact with any other leprous person. He also mentioned, as a not unlikely source in a few instances, vaccination. In the case of Father Damian, he thought the probable source of the infection was through mosquito bites.

His conclusions were: 1, that there was no warrant for the popular theory that leprosy was a contagious disease; 2, the disease was not contagious in the ordinary acceptation of the term, or as that word was applied to small pox, syphilis, etc.; 3, it was probably due to the presence of a bacillus; 4, there were strong reasons to suspect that this bacillus might be introduced into the system by way of food, especially fish; 5, there was evidence that the disease might under favorable conditions be transferred from one person to another; 6, heredity probably accounted for a share of the cases; 7, there was no necessity for segregation; 8, there was far more reason for placing restrictions about patients with syphilis and tuberculosis than about those suffering from leprosy.

The paper was discussed by Drs. Coan, Fernandez, and L. L. Seaman, who in general seemed to agree with the author.

Tracheotomy without the Use of the Tube.—Dr. Edward von Donkoff read the paper. He had for seventeen years performed tracheotomy without the use of the tube and cannula in ordinary cases. This was on account of the difficulties and dangers attending the introduction and wearing of the cannula. Who had not seen diphtheritic material pushed down by the cannula, particularly when introduced by a novice? Who had not known of sad results from failure on the part of attendants to secure prompt removal of the obstructing material which might enter the opening when the cannula was worn? Consider also the ugly wounds and scars which had at times resulted from wearing the tube. In short, except in special instances, he could not understand why the use of the tube should be persisted in.

The author kept the opening patent simply by ligature, one on each side, fastened behind the neck. There was no danger from undue tension. Very little after-management was required. The watchman was given a dull forceps with which to remove any membrane which might present itself at the opening.

Etiology of Hernia.—Dr. Thomas Manley presented a specimen obtained in a case of strangulated inguinal hernia. The operation was followed by recovery. He remarked, as to the etiology, that he had never seen a case, in young or old, where the adhesions of the sac were not marked; which led him to believe that the way for the future hernia was always paved with the descent of the testis, although actual protrusion might not take place at that time.

Dr. Manley also presented a portion of hernia and the uterus containing fibroids, from a case of very large ventral hernia which had followed a laparotomy performed by some surgeon four years before. Great difficulty was experienced, in operating for the hernia, in returning and keeping the intestines in the abdomen. During the operation some uterine fibroids presented through the opening, which he shelled out. The patient died, and at the autopsy the uterus was found to contain many fibroids, and it was his belief they might have been removed successfully per vaginam at a subsequent operation, and thus the patient would have stood a better chance of recovery.

Quinine is Too Cheap.—Dr. Keen says that we are becoming a nation of quinine eaters, and he attributes the growth of the habit to the fact that the drug is so cheap.

Remarkably Condensed Description.—The writer of an article on "Errors in Diagnosis," in an English medical journal, managed to embrace the whole subject in only three thousand words.

A Case of Hysteria in a Child Six Years Old is reported by Dr. Bailton in the *Lancet*, No. 3,554. The nervous symptoms followed an attack of influenza.

Clinical Department.

DOUBLE SYNCHRONOUS THIGH AMPUTATION FOR GANGRENE IN A CASE OF CHRONIC NEPHRITIS—COMPLETE RECOVERY.

By R. CRAIG FALCONER, A.M., M.D.,

LEXINGTON, KY.

CAREY C——, colored, aged fourteen, was brought to St. Joseph's Hospital, May 5, 1891, with the following history: He was a healthy, robust boy until October 4, 1890, when he was taken sick with pneumonia, kidney trouble supervening, the illness lasting about two months. Three weeks after convalescence his feet and legs began to swell, and were, the boy's father states, pricked with needles to allow the fluid to escape. But they continued to go from bad to worse till they became enormously swollen and "shone like glass." His feet and legs were next bathed in some domestic lotion—I believe made of mullein weeds—and according to his father's statement the swelling subsided and the feet and legs turned black. Then a sore developed on the right knee-cap, subsequently another on the inner aspect of right knee-joint. When I saw the boy for the first time, in the forenoon of the aforesaid day, his feet and legs were extensively gangrenous and infested with swarms of larvæ. His left leg, from the sole of the foot nearly to the upper third of the thigh, looked as though it had been charred, while his right leg was in a somewhat similar condition and almost disarticulated at the knee and ankle joints; the tibia and fibula being bared for half their lengths. He was emaciated to a marked degree, and still had a cough. Kindly assisted by Drs. W. A. Brock, D. H. Keller, Milton Edmonson, and T. A. Jones, I amputated both thighs, the left one at the upper third and the right one at about the junction of the middle and upper third. As soon as I had transfixed one thigh, arrested hemorrhage, secured flaps, and inserted drainage-tube, Dr. Keller did the suturing, while I proceeded to amputate in like manner the other thigh. The operation, which lasted about three-quarters of an hour, being finished, and the stumps dressed with iodoform sublimate gauze and cotton, I gave the patient a hypodermic of whiskey, had him wrapped in blankets and placed in bed surrounded by hot bottles. Ether was the anæsthetic used, as we found that the patient could not bear chloroform. He reacted from the etherization in due time and was bright and cheerful. In the evening, about three hours after the operation, his pulse was 120, temperature 101° F.; there was slight oozing of blood from the right stump. On the following morning his pulse was 130, temperature 103⅔° F. The dressings were removed and the stumps irrigated with carbolized water. His pulse, from the day of the operation to about twelve days afterward, varied from 120 to 140, and his temperature from 101° to 105° F. The pus was not as abundant as we might expect to find it in such a case where the tissues were so diseased. Drainage continued good, and the tubes were removed about the twelfth day after the operation. While there were both retraction and sloughing in each stump to the extent of exposure of the bones, this process progressed to a greater degree in the left stump than in the right one. To-day both stumps are entirely covered by sound and healthy tissue, and the boy is perfectly well, going to school every day, and weighs much more than he did just before the operation, if not more than ever. At present he has no albuminuria. As a tonic I gave him syrup of albuminate of iron and quinine.

Counterfeit Mummies.—Seventeen mummies, recently purchased at a cost of $200,000 by the Berlin Museum, have been shown to be of recent manufacture and the handiwork of some wily Arabs of Alexandria.

A CASE OF POISONING WITH PHENACETINE.

By A. M. FERNANDEZ DE YBARRA, M.D.,

PHYSICIAN TO THE NORTHERN DISPENSARY, NEW YORK.

ON December 19, 1891, I was called to attend Mrs. V——, the janitress of the flat house where I live, who was suddenly taken very ill. The husband of the woman told me she had drunk some porter and beer the night before, and when she awoke in the morning felt an intense headache. He went to a neighboring drug store and asked for some "headache powders" for his wife. He got three of them, and as soon as he reached home he dissolved one in a little water and gave it to the sufferer. No relief of the headache following, he gave, a quarter of an hour after, a second powder. Five minutes later he was surprised to see his wife in convulsions, and complaining of a terrible pain in her heart.

When I saw the woman she was pale, cold, and perspiring profusely, with both her hands over the precordial region, the respiration very much reduced in number, pulseless, and voiceless.

Suspecting an overdose of antipyrine, I asked the husband to let me see the so called "headache powders," and sent him to the drug store with my professional card to find out as soon as possible what they were made up of, and the quantity of the ingredients in each powder.

The drug clerk said the powders contained "only phenacetine," and ten grains of it each.

All the toxic symptoms seeming to me very much like those produced by chloroform narcosis, I gave the patient a few inhalations of nitrite of amyl, and administered the necessary antidotes to combat the depressive action on the heart; but not until an hour after could I feel sure that the danger was over.

This clinical case illustrates three very important points, viz.: 1. That phenacetine is not so harmless as usually believed; and if we stop to think for a moment, we shall see that the certainty and great rapidity with which it acts as an antipyretic, and its prompt and striking action as an analgesic, clearly indicate its powerful effect on the heart. A French authority has already pointed out that all heart-tonics are heart poisons. 2. The unreliability of proprietary articles, which, by becoming popular, may give rise to unscrupulous imitations. 3. The very bad custom among druggists of prescribing themselves powerful drugs, with whose therapeutic actions even the professional mind is not yet entirely acquainted.

140 WEST TENTH STREET.

A CASE OF ERYSIPELAS.

By G. TUCKER SMITH, M.D.,

U. S. NAVY, MARE ISLAND, CAL.

AN interesting case of this disease came under my observation last summer, of which I submit a brief clinical outline.

D——, machinist, aged thirty-one, native of America, weight one hundred and eighty pounds, family history and previous health good, presented himself for treatment July 20th. Two days before, while at work in the erginе-room, he slipped and fell, striking his left hand on a sharp rusty nail and sustaining a deep lacerated wound of the thenar eminence. This was cleansed and dressed soon afterward. The wound now looked indolent and unhealthy and caused a sharp pricking pain. It was irrigated with a bichloride solution, and a layer of bichloride gauze buttered with vaseline put on. Temperature and pulse normal, bowels open.

July 21st.—The pain continuing, the dressings were removed. The wound presented the same appearance, but a typical erysipelatous blush could be seen spreading from its margin upon the forearm. The eruption was dusted with zinc oxide and the arm swathed in antiseptic gauze. Tr. ferri chloridi, ♏ xxx., ordered every two hours. Temperature and pulse normal.

July 22d.—The eruption extended itself with great rapidity, involving the whole circumference of the forearm with its upper margin at the elbow-joint. Numerous blebs, both single and confluent, appeared, with a copious watery discharge. The œdema was considerable, but firm on pressure, and, though repeatedly taken, the temperature and pulse remained normal.

July 23d.—The upper margin reached as far as the middle of the arm, but the disease now took a downward course, involving the whole hand. The discharge became simply enormous, saturating the dressings and bedding and wetting the deck below his cot. The heart's action here commenced to lose its force, the pulse becoming slower and weaker. Milk-punch and nourishing diet were ordered, and dressings of equal parts of camphor water, ether, and laudanum had a soothing effect.

July 24th.—The pain becoming almost intolerable, and detecting for the first time that the swollen limb was less tense on pressure, a number of free incisions were made over the dorsum of the hand and forearm, affording almost instant relief. The discharge continued free, but there were no evidences of pus, showing absence of phlegmon. Temperature normal, pulse very weak, the patient fainting while the dressings were being put on.

July 25th.—The adynamia increasing, a fatal termination was feared; but by careful nursing and the constant administration of stimulants, aided by a robust constitution, the critical stage was tided over, and after two days he went steadily on to recovery.

The points, then, of interest in this case were: 1. The absence of pyrexia; the thermometers were of proven accuracy, and repeated observations at regular intervals showed no elevation of temperature from first to last. 2. The enormous amount of the discharge. 3. The value of alcoholic stimulation; in this case probably saving a life.

A CASE OF PERFORATIVE APPENDICITIS COMPLICATED BY PREGNANCY.

By FREDERICK H. WIGGIN, M.D.,

NEW YORK.

At the present time so much attention is given to appendicitis that the report of the following obscure case will perhaps be of interest.

On July 21, 1889, I was called to see Mrs. A. V——, a delicate-looking woman, twenty five years of age, married. She had been ailing for some time, was constipated (this being her habit), had not menstruated for three months, and had a great deal of nausea, especially in the morning. A diagnosis of pregnancy was made, and oxalate of cerium and compound liquorice powder ordered.

On the 24th the nausea had not been relieved, constipation continued, and viburnum compound and an enema were ordered. On the 26th, as the bowels had not moved, and nausea was more marked, I ordered calomel $\frac{1}{10}$ grain, sodium bicarbonate, one grain, half-hourly, for ten doses, then an enema. The pulse at that time was 100, temperature 99° F. At a later visit the patient was found to be more comfortable, and had had a small, scybalous movement.

On the 27th, nausea continued, and for the first time the patient complained of pain at McBurney's point. No tumor could be made out, and the pain was not increased by pressure. Temperature 100° F., pulse 106. Appendicitis was now considered to be the cause of the trouble. A consultation was had, but no agreement reached as to the diagnosis.

On the 28th the patient had had a fairly comfortable night. Pain at McBurney's point had disappeared, and was now complained of over the left ovary. No tumor or dulness on percussion could be made out. There was slight distention of the abdomen, and the muscles were somewhat rigid. Another consultation was had and the diagnosis was still not concurred in. During the afternoon the patient had a chill, and when seen an hour later had a temperature of 103° F., pulse 126. Diagnosis of perforation of the appendix was now made. Operation was proposed, but friends declined to allow it. General septic peritonitis developed, and the patient died on the 31st.

Autopsy. — On opening the abdomen evidences of general septic peritonitis appeared; the appendix contained a fecal concretion about the size of a hazel nut, formed in concentric layers. It had cut off the circulation—the appendix, which was gangrenous. Perforation had taken place at the junction of the appendix and cæcum. A three months' fœtus was found in utero.

The points of interest in this case were: The pregnancy, which might have accounted for the nausea; the absence of tumor, of dulness on percussion, or marked tenderness in the right iliac region; the changing character of the localized pain, which was first on one side and then on the other, leading some of the physicians who saw the case to the opinion that the pain was due to ovaritis, and that the trouble might have been caused by an attempted abortion; the fact that the patient was walking about until within five days of her death.

In this case, if laparotomy had been performed when the diagnosis of appendicitis was first made, the patient would probably have been saved. It is of great importance that the general practitioner should come to understand that an exploratory laparotomy for the purpose of making a diagnosis is not, in proper hands, a dangerous or difficult operation; and, instead of wasting valuable time in refinements of differential diagnosis, as soon as it becomes clear that he has to do with a case of grave intestinal trouble, he should call to his aid a surgeon.

A CASE OF VARICOSE ABDOMINAL VEINS IN A BOY OF SIXTEEN.

By R. ELLIS, M.D.,

DANBURY, CONN.

The patient is a robust lad, aged sixteen, with an excellent family and personal history. He has always been in excellent health until after the Blizzard, when he was sick in bed for three weeks. During the Blizzard he thinks he worked too hard as a grocery delivery clerk, and as a result strained himself. Two days after the Blizzard he felt "heavy pains" in both limbs, and in a few hours they were much swollen. A physician was called, who treated him for rheumatism. He was in bed three weeks, complaining solely of pain in both limbs. He says they were cold, blue, heavy, and symmetrically swollen; his greatest pain was over the great vessels. Both limbs recovered at the same time. He suffered in no other way, save that in the beginning there was dull pain over his stomach. The symptoms proved conclusively that his trouble was phlebitis. Four weeks after the attack ended he noticed a "blue spot" in the left inguinal region, which entirely disappeared under pressure; he consulted his physician again, who diagnosed "rupture" and ordered a truss. Six weeks later, observing no symptoms meanwhile, he noticed the veins of his abdomen were enlarged. He thought nothing of this until, two years later, the "heavy, tired pain" became so severe, especially at night, that he judged it best to consult another physician.

As he undressed I noticed his truss, and requested him to remove it to facilitate the examination. There was absolutely no sign of a hernia; the "blue spot," which was evidently but a dilated vein, was mistaken by his former medical adviser for a hernia. The truss, which he had worn for two years, fitted so tightly that it greatly increased the tension of the veins on that side.

Now comes the interesting question of etiology. What caused this severe phlebitis in both limbs? Why, after perfect recovery and no venous enlargement, did the abdominal veins become varicose in ten weeks? My limited library does not contain the record of such a case in one so young. I believe from the history of the case

that the attack originated from intra-abdominal obstruction to the venous current. I cannot say whether the obstruction was due to some trouble without the veins, in the coats of the veins, or within the veins. The possible causes are easy to give, the true one difficult. In reference to the varicose abdominal veins, the reason for their existence is clear, if the phlebitis in the limbs was due to intra-abdominal venous obstruction, but if not, the reason is obscure.

The appearance of the abdomen is like that of the case given in Bryant's "Surgery," of collateral venous circulation due to an obstructed inferior vena cava.

A CASE OF HYDROPHOBIA.

By SIDNEY I. SMALL, M.D.,

SAGINAW, MICH.

I AM led to report the following case, not for the purpose of advancing any new theory, but from a sense of duty to record it among statistical data.

On the afternoon of July 4, 1891, Maurice G——, aged seventeen, in attempting to quiet two quarrelling dogs, fell, and was bitten by one of the dogs, just above the left eye. But little attention was paid to the wound which healed readily, and the young man continued at work until Wednesday, July 30th, although for five or six days previous to this he had complained of feeling badly, having slight fever, and occasional pains in the region of the wound; and his sister, with whom he boarded, noticed that he seemed greatly depressed, disinclined to talk, and at times very irritable. On Wednesday when he quit work these symptoms had increased, and he complained of stiffness in the muscles of the neck, occasional choking sensations, and pain in the wound, extending over the side of the head. Thursday noon he experienced difficulty in drinking. His condition grew rapidly worse during the afternoon, and when I saw him at seven o'clock he could swallow liquids only by the greatest effort. The area of redness about the wound had increased, the eye was congested, and the pain severe. I passed him a glass of water, which he took in both hands and carried to within a few inches of his lips, where he held it a short time, shuddering, and then by a sudden movement of the hands, at the same time jerking his head forward, he seized the glass in his mouth and took one swallow. The act of swallowing caused a spasm of the pharyngeal and respiratory muscles, a "catching of the breath," resembling that produced by an affusion of cold water, and followed by a relaxation of the muscular system, and an appearance of great exhaustion.

Realizing the grave nature of the case, I asked Dr. Sample and Dr. Connery to see it, and they continued with me in charge until the close. The patient rested but little Thursday night, but continued to get worse, and when we visited him Friday morning the sight of water, a drop upon the skin, or the sound of pouring it from one vessel to another, a draught of air, or a strong light, was sufficient to produce a spasm. He was unable to swallow his saliva, but expelled it with great difficulty, and occasionally vomited a greenish-brown liquid. The convulsions spread to all the other muscles, becoming tetanoid in character.

Friday night there appeared some delusions which, toward morning, increased to wild delirium. In a few hours this gave place to paralysis and coma, and the patient died at ten o'clock Saturday morning. The temperature ranged about two degrees above normal.

A carefully-made autopsy by Dr. Connery discovered nothing striking. The blood was fluid, more so than usual, the brain congested, and vessels dilated.

The treatment was by curarine, hyoscine hydrobromate, and morphine hypodermically, and chloral by the rectum, and the success was no greater and no less, I suppose, than has been reached by others, according to authentic records. I attach a table showing the amounts given, and the intervals, with the effect produced, or, to speak more accurately, the condition which prevailed at the time. Amyl nitrite was also tried, but disappointed us with transitory and slight effects. In another case I think I should try curarine again, but in larger doses.

Our attempts to trace the history of the dogs were only partially successful. Both disappeared, and of the one which gave the wound nothing more has been heard. The other one, which had been bitten in the fight, was found Saturday morning, August 1st, in an outhouse at his home. He appeared dull and indisposed to move, but when roused was very irritable and inclined to bite. He was secured and placed in a room, furnished with food and water, and his behavior noted by Dr. Connery, to whom I am indebted for the subsequent history. The animal soon became extremely restless, howling almost constantly, beginning with a short note, and ending in one very much higher, prolonged, and having a peculiar, metallic ring. The jaw drooped, allowing the mouth to remain partially open, and this condition was followed by so great weakening of the muscles of deglutition as to prevent swallowing. The statements in regard to the great dread of water were not true here, for the animal apparently made great attempts to swallow, but was unable. There was, from the first, unsteadiness of gait and movement, with increasing weakness, until he was unable to stand, and he soon became comatose, and died Sunday afternoon. The symptoms closely resembled those of acute ascending or Landry's paralysis. The post-mortem examination showed great hyperæmia of the dura mater and cortex. The larynx, trachea, and lungs were also much congested. The stomach was partly filled with hay, bits of wood, cinders, and hair.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DESTRUCTION OF MICRO-ORGANISMS BY AMŒBOID CELLS—DEATH OF PROFESSOR JOHN WOOD—THE GROWTH OF THE PROFESSION—LADY DOCTORS—GIFTS TO THE LONDON UNIVERSITY.

LONDON, January 2, 1892.

In a lecture recently delivered in the theatre of the College Laboratories on the Embankment (maintained by the Royal Colleges of Physicians and Surgeons), Dr. Armand Ruffer gave an account of some further researches which he had made on the destructive action of amœboid cells on micro-organisms. The result of these further observations, he said, was to confirm him in his former opinion, that the destruction of micro-organisms in living tissues is accomplished by the cells of the body, and by the cells only. His recent experiments were all made with the virus of quarter-evil, the *bacillus Chauvæi*. Instead, however, of using guinea-pigs, which took the disease readily, he inoculated rabbits, which were immune against quarter-evil, and therefore lent themselves well to the study of the effects on this virus of the living fluids and cells. If the immunity of rabbits were due to the fluids of the body not furnishing sufficient nutritive material, the bacilli of quarter evil ought not to grow at all—or but sparingly, at any rate—in those animals. If the immunity were due to some bactericidal power possessed by the rabbit's fluids, then degenerated bacilli should be found in the fluids near the point of inoculation. If, on the other hand, the rabbit's resistance were due to the action of the animal's cells, and not to the action of fluids, then the bacilli should grow freely in the fluids of the animal's body, but degenerate in the interior of amœboid cells.

Dr. Ruffer found that both in guinea-pigs and immune rabbits the bacilli commenced growing as soon as they were introduced, and that the leucocytes gathered to the spot where the micro-organisms had been introduced. The leucocytes were attracted to the spot by the chemical poisons secreted by micro-organisms, and they violently attacked the latter, took them into their interior, and destroyed them. The cellular emigration at the point of inoculation varied inversely to the quantity and strength of the virus introduced, but was in proportion to the length and curability of the disease. When a large quantity of extremely virulent bacilli was injected, the emigration of leucocytes was slight or totally absent, but it was more marked when only a few virulent bacilli were introduced, or when the quantity of virus introduced being large, its virulence had been previously diminished. Whenever, from any cause, mechanical or chemical, the leucocytes were prevented from reaching the virus, the disease invariably progressed and the animal died. (This was well demonstrated when, after enveloping the virus in filter paper and allowing it to remain under the animal's skin, the protection of the paper was removed.) When the leucocytes were repelled by the action of lactic acid on one side of the body, the disease only developed on that side, and when the cellular emigration was arrested by injecting the bacterial poisons into the blood-stream, the disease progressed with an appalling rapidity. What was observed with regard to cellular emigration, however, by no means applied to the other necessary accompaniment of inflammation, viz., exudation; it would rather appear as if the two stood in some inverse relation to one another. Compare, for instance, the thin sanguineous exudation of a rabbit dying in twelve hours from the inoculation of the bacillus chauvæi, and the thick, tenacious material which accumulated around the virus inoculated into a resistant animal. Was that not sufficient evidence that, in that disease at least, exudation of fluid was always more marked when the disease was most virulent? But in spite of the enormous quantity of this exudation (supposed by some to have strong bactericidal powers), there was not a sign that the micro-organisms were injuriously affected by it; on the contrary, they grew and thrived excellently well.

Another point which stood out clearly was that, when once the animal substances produced by a micro-organism had penetrated into the blood, the poisons secreted by the same micro-organism in other parts of the body failed to attract leucocytes. Thus, on injecting a drop of the culture of the bacillus pyocyaneus into a rabbit's eyes, the leucocytes emigrated to the spot in large numbers; but when the poisons produced by this bacillus were already circulating in the blood, the leucocytes no longer left the vessels. The same result was obtained when the bacillus Chauvæi was injected both subcutaneously and intra-venously. In the case of the bacillus pyocyaneus, there was some evidence to show that the leucocytes were actually paralyzed, for Charrin and Gamaleia had found that the application of croton-oil to the ear of an animal poisoned with the products of the bacillus pyocyaneus was not followed by inflammatory reaction at the point where the oil was applied. This explanation, however, did not hold good for the results obtained with the bacillus Chauvæi. Here the leucocytes in the blood-vessels and the spleen were extremely active, but absolutely powerless to emigrate into the surrounding tissues, in order to attack bacilli of the same species. Their absence of emigration, however, was not due to some change in the vessel-wall, for the leucocytes left the vessels to attack another bacillus—b. pyocyaneus. Similarly the leucocytes of an animal suffering from anthrax declined to attack anthrax bacilli, bnt cheerfully accepted any other diet offered them. Here again, the refusal to emigrate was not simply due to spasm of the vessels or any other vascular cause, as these same cells emigrated freely when any other stimulus was applied. The reason for these apparent anomalies was that, so long as the chemical substance which attracted the leucocytes was present outside the vessels only, the cells emigrated to the spot where this chemical substance was to be found; but as soon as this chemical substance was present in equal or larger quantities in the vessels as in the surrounding tissues, the leucocytes no longer attempted to leave the vessels.

The death is announced of Professor John Wood, who was for many years a member of the surgical staff of King's College Hospital, and lately retired as Consulting Surgeon. Mr. Wood held many important appointments in his time, including those of Professor of Surgery at King's College, and examiner at the College of Surgeons, the College of Physicians, and the Universities of Cambridge and London. He made several important contributions to surgical literature, and one of the operations for the radical cure of hernia is associated with his name. Professor Wood had been in ill-health for some time, but his death will cause a shock to many of his old pupils and confrères, who have been accustomed to look up to him as a skilful and upright surgeon, and as a valued friend.

The rapid growth in numbers of the profession is strikingly illustrated by a glance at the new volume of the Medical Directory just issued. This now comprises more than thirty thousand names—nearly two thousand more than in the edition for 1888. This means that there is one doctor to every ten or eleven hundred of the population—a proportion quite high enough to render the obtaining a decent livelihood by members of the profession a matter of ever-increasing difficulty. This number includes the medical ladies, or lady doctors, who are now becoming sufficiently numerous to cease to attract special comment. Several of the medical ladies have married since entering the profession, and the change of name thus made renders it somewhat difficult to trace their identity. One lady appears in the body of the work under one name and in the appendix under another name, with a note referring to the former entry—a change probably due to marriage. From a glance at "Churchill's

Medical Directory," it is impossible to say whether any lady whose name appears therein is married or single. The editor of "Kelly's London Medical Directory" is more liberal in giving information, and considerately prefixes Miss or Mrs. to the names of some of the lady doctors in his publication. This is in accord with the style of door plate generally affected by lady doctors, who usually refrain from using the prefix of Doctor.

Lord Sherbrooke (better known by his former name, Mr. Robert Lowe) has given a thousand pounds to the University of London, and the Earl of Derby has promise l a similar sum. These gifts are to be devoted to establish a prize essay and Granville scholarship, respectively.

THE DUES OF THE NEW YORK ACADEMY OF MEDICINE.

To the Editor of the Medical Record.

Sir: The letter from "An Impecunious Fellow," in your last issue, was to the point as far as it went, but the writer acquiesces too readily in the increase of the dues, and I cannot agree with him in his concession of the right of the present governing clique to run the institution as they please, and then call on the rank and file to foot the bills. They are the servants of the fellows of the Academy, and it is their business to manage the affairs of their masters as economically as possible. Instead of this, they seem to be trying to see how big a splurge they can make in the new building, apparently attempting to emulate their neighbor, the Century Association, as far as display goes, without, however, giving the fellows any equivalent for their money in the shape of club conveniences.

The admirable protest of Dr. Amidon against the favoritism that is so palpable, not only in the selection of men for discussion of papers, but also in the snubbing of the younger fellows who have papers to read but are put off by the autocratic section officers, until they get tired of waiting and take their contributions to some other society, is timely and pertinent. I would also commend to the serious consideration of the members his remarks concerning the way in which the offices are distributed among the insiders, for this has a bearing upon the question of the extravagance which necessitates increased dues or extra assessments. If the close corporation that now runs the Academy for its own glory (?) were broken up and a little new blood brought into the management, it is very possible that some of the present abuses would be done away with. An amendment to the constitution has been proposed, making every officer ineligible for reelection to the same office until one year after the expiration of his term of service. This would be an excellent provision, and it is to be hoped that those who favor reform in the society will do all they can to secure the passage of this amendment.

Another Fellow.

DYSPHAGIA IN PLEURISY, WITH EFFUSION OF THE LEFT SIDE.

To the Editor of the Medical Record.

Sir: I desire to call attention to a condition present in effusions of the left pleural cavity, of large proportions, which I have met with, but do not find mentioned in any reading to which I have had access, namely, dysphagia, or difficulty in swallowing. I have noticed it in three cases, and my attention was called to it by the patients themselves. These cases all presented the true signs of liquid, and more especially that of cardiac displacement. In one, where the "impulse" was readily felt in the right mammary line, the patient complained the most of the trouble in eating, or as she expressed herself, "I seem to swallow around something." In one case the dysphagia was relieved in a few hours after aspiration of more than a quart of liquid. In another the relief was gradual, as the effusion disappeared by absorption.

Latterly, I have had two patients at the same time, one with right, and one with left, effusion, both effusions of large proportions. While the case of the left pleurisy complained voluntarily of the trouble in swallowing, the patient with the effusion in the right pleural cavity had nothing of the kind, neither did close questioning elicit anything to that effect. Should another case occur with this symptom, as I conceive it to be of left pleurisy, I shall attempt a verification of my theory with the passage of a bougie.

My explanation is that of a displacement of the cardiac end of the stomach, carrying with it the œsophagus; leaving a sharp curve against which the food rudely impinges. This condition would theoretically happen with a displacement of the heart to the right mammary line, as in the most pronounced case before cited.

I should like to hear from the profession on this point.

Ralph Cross Huse, Jr.

THE TREATMENT OF A COLD.[1]

BY HENRY H. SCHROEDER, M.D.,

NEW YORK.

WE are not apt to choose a subject when about to address an assembly of medical men that refers to an everyday, commonplace malady. Yet it will possibly be of profit to us all if this brief paper is successful in drawing out a discussion from the members present. The subject is not such an unimportant one either, though it is neglected by the text books on clinical medicine, when we consider how frequently we are called upon to contend with colds and the resulting diseases. It will perhaps be permissible to digress, before speaking of the treatment, and inquire briefly into the nature and causes of the disorder.

What is a cold? Even in the present state of knowledge it is difficult to give a full and satisfactory explanation of all the phenomena of the disease. In common parlance, it embraces everything from a mild coryza to galloping consumption, and intelligent people tell you that some relative, having contracted a "bad cold," died after several months' or a year's illness, yet deny that consumption ever existed in their families. This is a point to be kept in mind when examining for life insurance, and close questioning as to the symptoms and duration of the sickness should be employed. It is to be feared that this promiscuous use of the term is not confined to the laity, for when persistently pressed for an explanation, how easy it is to unfold to a patient the mystery of their particular ailment by informing them that they have taken cold; this explains satisfactorily to them all the pains and aches so often disagreeably indefinite to the attending physician. In the course of an ordinary cold there is invariably a certain degree of febrile and inflammatory action, and many of the symptoms which usher it in, precisely resemble those which occur when some special form of fever or severe inflammation is about to attack the patient. They may not be so severe, but the difference is one of degree. The existence of prodromes, the chilly sensations, loss of appetite, depression and appearance of fever prior to the development of the local manifestations, the persistence of the local inflammation after the temperature has fallen, all serve as good evidence that the disturbance is not due to a mere local inflammation, but to a general affection. There are people who are incessantly catching cold on the slightest provocation, but who suffer very little from the general symptoms. In these cases there are local sources of irritation, some chronic inflammation, thickening, atrophy, new growth, or deformity about the nasal passages, or chronic inflammation of the mucous membrane of the pharynx, larynx, or bronchial tubes. In all of these an acute attack on top of the old is very easily aroused, as the structures being diseased, are influenced by conditions that would otherwise be inert.

How do we take cold? At this question, forward comes the time honored prejudice in favor of a very low temperature. Exposure to cold with old age, vicious habits, constitutional defects and many other causes, may predispose to colds by undermining the powers of resistance already weakened. Excepting these cases, however, the rule holds good that a person may be subjected to an intense frigidity, even to the freezing of the extremities, without taking cold. A moderately low temperature, just above freezing-point, and a moist atmosphere are the most favorable conditions, especially in the form of a draught. Some years ago I happened to be a member of a United States surveying party out among the foot hills of the Rockies. During the winter, when the atmosphere usually remained about zero, and thirty to forty degrees lower during the blizzards, for the winter was severe even for that region, our only shelter was the canvas tents. The clothing and blankets were cut down to the minimum amount on account of the difficulties of transportation, yet the only man who was afflicted with a cold, was one who had persisted in bathing in a natural hot spring near which we were camped for a short time. Even with the favorable conditions present, a cold does not often follow exposure of the whole body; receiving a draught from an open window on a portion of the body, and chilling of the feet in damp weather are the most fruitful sources. So it is seen that the excitation occurring at a certain locality results in inflammation in another part of the body which happens to be weakened or hypersensitive, and that is generally, in this climate, in the respiratory tract, though it may exist elsewhere, as in a rheumatic joint or at the seat of an old pelvic peritonitis. Those examining for life insurance find in some cases a transient albuminuria, and even an occasional hyaline cast during or immediately after a cold. Though such an applicant may be favorably recommended after a short postponement and furnishing several normal specimens of urine, are we sure that this condition is not a signal denoting a more or less asthenic state of the kidneys, which will be liable at some future time to invite more serious changes? These effects are probably attained through the agency of the central nervous system which governs the function of heat-production and nutrition. As a result of the cold, moist draught on some part of the body, this function is disturbed, and the central nervous system still possessing the same amount of force and action, must have an overflow through some other channel. Just as that part of a dam capable of the least resistance is broken away first by too much pressure from the reservoir, so is the weakest point chosen for the exhibition of the increased amount of heat-production and nutrition; but the heat is developed faster than it can be carried off, or the process by which it is eliminated is interfered with for the time, and inflammation and fever are the results. But we must leave the most interesting part of the subject to discuss the treatment of colds.

Prophylaxis will prove most valuable to our patients, if we can persuade them to be guided by its precepts. It is safe to say that the people of this country suffer more from an excess of food than from scarcity, but it is perhaps absurd to entertain the idea that we can prevail upon them to be careful in this respect; yet if we can induce them to limit themselves to some extent to the proper quantity and quality of food, a great deal will be accomplished, for we repeatedly see inflammations of the upper air passages, which are much aggravated, if not actually provoked, by indigestion. A good digestion and proper food means a well-nourished body which can ward off disease. An excess of alcoholic beverages has a debilitating effect upon the tissues in general, and it is a well known clinical fact that inflammations and fevers in those ad-

[1] Read at a meeting of the Society of the Alumni of the Charity Hospital, January 6, 1892

dicted to this habit, respond very reluctantly to our treatment. These persons also are more apt to recklessly expose themselves to the inclemencies of the weather. Regular action of the bowels should be attended to for this as well as many other reasons, for if the excretory organs are kept up to their work, the deleterious substances which tend to depress and vitiate are removed. This is of great importance to those who have a predisposition to gout or rheumatism. Any pernicious substance within impairs the vitality of the tissues, and renders them more susceptible to external influences. Impure air and poor hygienic surroundings are abuses which prevail on all sides in these days of dark, steam-heated apartments for dwellings and offices. Attempts to remedy such evils, however, would discourage the most persistent of us, yet can you conceive of a more debilitating or enervating effect, than that produced by such surroundings on the general health as well as the mucous membranes? In nine out of ten of these offices, weary, overtaxed brain-workers are struggling to exist in air that would almost suffocate the hardiest and most vivacious bacillus. Exercise is a measure that we will meet with more success in persuading our patients to adopt, and the men who occupy the offices and rooms just mentioned, can by this means counteract many of the poisonous effects caused by their unhealthy surroundings during working-hours. A long, brisk walk to and from their place of business will be of great benefit, and riding in the close, crowded, draughty, and uncomfortable elevated cars will be avoided. But of all the means by which we may inure our bodies to variations of temperature and other unfavorable conditions of the weather, let me heartily recommend the cold bath, especially if taken in the morning. How often after a broken night's rest, or perhaps no sleep at all, I have felt refreshed and invigorated by the morning sponge-bath which I have accustomed myself to take every morning with a marked beneficial effect. A cold bath followed by a cup of coffee, is the best substitute for sleep that I know of. It is an important agent in the preservation of health and giving immunity from colds; but unfortunately some are debarred the use of it on account of the depression which they experience, though this may often be prevented by friction with a rough towel. In these cases there is a deficient heat-producing power, which is due to old age or debility arising from some constitutional disease.

The majority of people fondly cherish the idea that they become exempt from colds by wearing an inordinate amount of clothing, but I do not hesitate to say that more are contracted by having too much on than too little. We must remember that during the greater part of the time we live in a temperature which is about equal to a mild summer heat, and that if burdened down with flannels, the skin will be more or less moist with perspiration. Now, when a draught of cold air reaches any part of the body, a sensation of chilliness is experienced in spite of the layers of wool, and this marks the onset of a cold. The prevailing mode of dress for women is extremely faulty, and it is no uncommon sight to see a ridiculous fur cape over the shoulders of one wearing low-cut shoes and thin silk stockings. The most vulnerable point for the reception of colds is the feet, not the chest. As Bosworth aptly remarks, "the best possible place to wear a chest-protector is on the soles of the feet," and "the worst possible place is over the chest." He maintains that excessive protection of one portion of the body at the expense of another, invariably results in some weakness, without protecting that part especially, and is a vicious custom of clothing. Advise your patients to wear moderately heavy woollen underwear, evenly distributed, and to rather depend for freedom from colds upon making their bodies hardy and vigorous.

All this good advice, however, will be very little heeded, and our practices suffer no diminution from a generous dispensation of it. Men hustle about town in their mad rush for business, having not the slightest regard for the preservation of health, and the ladies will wear top-heavy clothing and make the feet appear small. So it becomes necessary to adopt curative, or, as some will prefer to term them, palliative measures.

If our attention is called to the case in the very beginning, an attempt should be made to abort the cold, and for this nothing is better than the old-time treatment, consisting of a hot foot-bath, hot punch, a ten-grain Dover's powder and five grains of calomel. To this some add quinine, but I never do, as the patient has already had enough to cause a dizzy brain in the morning. As soon as possible after the foot-bath, the patient should be put between the sheets and kept there until well. If there is much perspiration, the skin should be dried, using moderate friction at the same time. I do not think that we often succeed in aborting an attack unless it is a mild one, but the above treatment, applied at any time in the first part of the disturbance, seems at least to mitigate the subsequent course. The physician is not generally called until the local symptoms have developed, and they are so distressing that they receive most of the attention. Still, a great deal can be done in the way of general treatment. I always begin, be the patient old or young, with a dose of calomel, varying according to the age, and followed by a saline laxative in the morning if necessary. We may consider this the best part of the whole treatment, for it hastens the waste occasioned by the febrile diseases, and causes the elimination of the products through the intestine. A sedative is followed by a result which is grateful to the patient, and may consist of bromide, chloral or codein. There is always more or less fever, and if the tonsils are invaded there will be considerable: this can be mitigated by five-grain doses of acetanilide or phenacetin, every two or three hours, to an adult, until relieved. If there is much pain, the addition of the caffein alkaloid will greatly enhance the value of the phenacetin. When the bronchial tubes are inflamed, there is in the febrile stage a dry, hacking cough which is extremely aggravating, and a soothing expectorant mixture is indicated. One which has given entire satisfaction to my patients consists of the spirits of chloroform, spirits of camphor, codein, and muriate of ammonia in glycerine or sirup of tolu. But after the expectoration begins to be free, the so-called "cough mixtures" are worse than useless, serving only to dull the appetite and derange the stomach. When the patient is a child, the fretfulness and incessant crying are extremely annoying to those around, and irritating to itself. To quiet it, two or three grains of phenacetin and about five grains of sodium bromide, repeated several times if necessary, are quite effective. Aconite and belladonna have been used by me with such a poor result, that I have consigned them to a "back seat." A gouty or rheumatic diathesis is at the bottom of the trouble occasionally, and in such a case fifteen grains each of salicylate and bicarbonate of soda has been of more use to me than any other remedy. Salol, vaunted as being of the highest value, seems to me to be only a weak edition of salicylic acid and the salicylate of soda.

Local remedies, varying with the part involved, soothe the angry mucous membranes and allay the inflammation, and are very useful adjuncts. The most frequent manifestation of a cold is an acute rhinitis. This consists of a congestion and swelling of the Schneiderian membrane, followed in a few hours by the secretion of a profuse, watery, acrid discharge which excoriates the skin about the nostrils. Insufflation of a powder consisting of boracic acid, bismuth, morphine, and camphor gives wonderful relief from this very disagreeable condition. Atropin, one-eighth grain to the drachm, added to the above, will stop the discharge almost immediately, but it leaves a sense of fulness which many object to. Hot nasal douches have been recommended, and it seems as if they might prove beneficial, judging from the effects of heat on inflammations in other parts. Inhalations of vapor from hot water containing iodine, carbolic acid or chloroform alleviate to a considerable degree. The menthol inhalers sold in the shops are also useful, and have the advantage

of being easily carried about, for we cannot expect to be able always to keep the patient in the house, though that would be of more benefit than any other measure.

The use of cocaine has come to be very popular as a remedy for relief in coryza, as well as some of the more chronic troubles, and it is not by any means confined to physicians, for I have seen druggists prescribe it over their counters, and also heard customers request it. I am glad to have an opportunity to strongly condemn its employment, except as a surgical expedient, though a small dose by the stomach for some such purpose as to arrest severe vomiting, does not occasion the delightful sensations that occur in many persons when applied to the nasal membranes, or given hypodermatically. One has only to see the wrecks of those who should have been foremost in the ranks, to learn that this is not a drug to be used for every trivial complaint. I am aware of two unfortunates with whom the habit originated from nasal applications alone. Then, again, a severe collapse has followed its administration by the throat and nose, and we are unable to determine in whom the idiosyncrasy lurks, until this alarming condition, or some other less grave nervous symptom, is provoked. After all, cocaine is of very doubtful utility in these cases, for the effect, though fascinating to such a dangerous degree, is very evanescent, and the reaction brings with it an aggravation of the patient's condition, which can only be relieved by repeated applications. In some of the books it is stated that the good impression produced is of two to four hours' duration, but these are exceptional cases, for it is generally only a half to one hour. Considering, then, the small amount of benefit derived, it is unjustifiable to tempt weak humanity with the most enchanting sensations ever produced by a drug.

As soon as the discharge becomes thicker and more tenacious, and there is difficulty in clearing the obstruction from the nasal cavities, the calibre of which is already narrowed by the tumefaction of the membranes, an alkaline spray, such as Dobell's solution, or glycerine and water in which Seiler's antiseptic tablets have been dissolved, brings away the yellowish-green, muco purulent matter. This cleanses the parts, and may be followed by an inhalation of benzoinol or some other liquid petroleum derivative, which we can use alone or with the addition of menthol, carbolic acid, camphor, eucalyptol, or several other drugs. Camphor and menthol rubbed together until a semifluid mixture results and added to the benzoinol, gives great relief. Oliver's vaporizing atomizer, made by Codman & Shurtleff, of Boston, is especially adapted for the administration of these compounds. Applications of nitrate of silver, sulphate of zinc, and other strong astringents are without value, and the use of chromic acid or any cauterizing agent can only be deprecated, for it is not warranted in a self limited disease which will probably last only a few days.

In severe cases of coryza the catarrhal inflammation may extend to the frontal sinuses, Eustachian tubes, or pharynx. Severe frontal headache is experienced when the sinuses are involved, and is very much alleviated, or entirely relieved, by the local application of heat. Eustachian catarrh needs no additional treatment unless the process extends to the middle ear, and I always employ counter-irritation in form of a blister as a preventive measure as soon as I make out any ear trouble, and feel confident that many ear-drums have been preserved from rupture by this means. For pharyngitis, alkaline and astringent sprays are indicated, but the ailment is often provoked or made worse by some other disorder which also demands treatment, whether it be a deranged digestion, a lithæmic diathesis, or a general debility. Liquid vaseline, with the addition of carbolic acid, salicylic acid, or iodine, in the form of a spray or vapor, is quite effective. It is to be kept in mind that the vaseline adheres to the mucous membranes for a length of time which has been found to be from two to three hours, whereas the watery sprays only bring the medicament in contact with the parts for fifteen to twenty minutes. Tonsillitis, like pharyngitis, is often a reflection of some other trouble, although excited by the cold. It is accompanied by pain of the surrounding parts, especially when the pillars of the fauces are stretched during the act of swallowing. Nothing has given more relief to this in my experience than a gargle of water hot as can be borne in the mouth, and repeated every one or two hours. It has, besides, a desirable effect upon the inflammation. In laryngitis we must depend upon a very fine spray, or, better yet, the vapor from the Oliver atomizer, which can be drawn into the larynx with the ordinary inspirations. The menthol-camphor already mentioned, possesses the desirable remedial qualities for laryngeal inflammation, with benzoinol as a vehicle, in the proportion of three to five per cent. When the trouble becomes subacute, carbolic acid, iodine, or eucalyptol may be substituted. In children, catarrhal croup sometimes ensues, but is easily controlled by use of an emetic, a rectal enema, $\frac{1}{30}$ to $\frac{1}{40}$ of a grain of morphine every hour until relieved, and hot fomentations over the throat. For bronchitis, counter-irritation by means of mustard over the chest is of great value. After the expectorant mixtures have done their part, inhalations of oil of tar, turpentine, eucalyptus, or turpentine, either with Beverley Robinson's inhaler, or in benzoinol with Oliver's apparatus, are very useful.

It is always best when treating children for colds, even if situated in the upper air-passages, to employ some mild counter-irritant, such as camphorated oil, over the throat and chest, and thus forestall the anxious mother who expects some such measure, and who will surely propose either goose grease, parboiled onions, or fat pork. Finally, it is frequently necessary to follow these disturbances with tonics. For the debility and prostration after very severe colds, quinine in small doses, combined with nux vomica and capsicum, and put up in capsules, makes one of the best. If anæmia also exists, iron should be added to the same combination. Alcoholic stimulants have to be exhibited with a generous hand when the patient is aged, feeble, or afflicted with some organic disease, for the debility and prostration may be so extreme as to prove fatal, and in such cases we cannot be too attentive.

Hermaphrodism.—The *France Médical*, October 23, 1891, gives a notice of Dr. Charles Debierre's recent work upon this subject, which has been undertaken solely for the following purpose: first, to prove that, from the anatomical point of view, the hermaphrodite is neither a monstrosity nor a freak of nature, but a creature devoid of ordinary development, that is, not developed sexually in conformity to its species. Physiologically, the hermaphrodite is a degenerate, impotent and sterile, imperfect in impulse and characteristic equilibrium, on account of unstable and perverted sex. Socially an unfortunate object, and much to be pitied, the hermaphrodite belongs to the dangerous classes, and society should be warned accordingly. Humanity is either masculine or feminine. The unhappy object of Dr. Debierre's study is neither man nor woman. Before the civil code it would be well to consider the hermaphrodite absolutely neuter, thus excluding the possibility of legal marriages in cases of doubtful sex.

A Curious Verdict.—A steam atomizing apparatus fell on a child in an English town and killed him, and the verdict of the coroner's jury was that he "died from shock following bronchitis and whooping-cough, caused through the shaking of the house by the firing of a gun at the Government proof butts on the Plumstead Marshes."

No Pay, No Cure.—A Maryland physician who had just sewn up a large wound in a man's leg, upon being refused a fee, cut the stitches and went away, saying that he didn't do any more work for nothing.

THERAPEUTIC RESULTS OF DIRECT ELECTRIZATION OF THE STOMACH.[1]

By MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY AND INSTRUCTOR IN CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

In a paper entitled "A New Method for Direct Electrization of the Stomach."[2] read before the New York Academy of Medicine on March 25, 1891, I promised to give more detailed results of the physiological and therapeutic action of this method at a later opportunity.

By the introduction of the deglutable stomach electrode direct gastro electrization has been, in fact, simplified and greatly facilitated. Thus I was enabled to treat quite a large number of patients by this method, and to make several experimental investigations besides.[3]

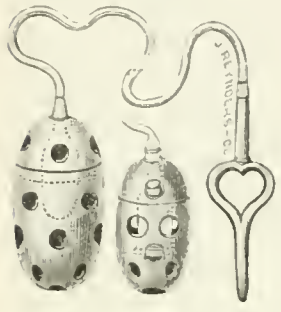

FIG. 1 — Deglutable Electrode. large size. FIG. 2.—Deglutable Electrode. small size.

Notwithstanding that my work on this subject cannot as yet be regarded as completely finished, I would now like to communicate the results already obtained, for I trust that they will prove of value in therapeusis, and a supplement to this paper can be issued without any inconvenience at a later period.

The literature of electrization of the stomach I have discussed pretty fully in the above-mentioned paper, but there are yet some points to be added in reference to direct electrization of the stomach which will be done later at the proper place.

In the administration of electricity I have made use of the two electric currents most commonly employed in medicine, viz., the faradic and the galvanic. As there were no rules when to use the one or the other kind of current, I in the beginning applied almost exclusively the faradic, this electric resource being most easily handled and found everywhere, only where there was no result whatever, or only a slight one obtained by faradization, did I take up the galvanic current. After a while, however, I thought that I had discovered one indication for the application of the galvanic current, and therefore administered galvanization at once in appropriate cases in the beginning of the electrical treatment.

Before discussing the proposed subject, viz., the therapeutic results of direct gastro-electrization, I would like to describe a few instances which bear upon the physiological efficacy of this means. In the above-named paper I mentioned several experiments which showed that the faradic current increases the amount of gastric juice secreted. This has been verified by Allen E. Jones.[4]

As can be seen from the experiments mentioned in my paper, the increase is, however, not very large, and I would like to add now that this increase must not be expected with mathematical certainty. Meanwhile, I had the opportunity to observe a case where the degree of acidity after faradization was lower than before. Here many factors enter into play, which sometimes are not very easily seen and taken into consideration. I think, however, I may conclude from my further experiments that the faradic current generally increases the gastric secretion. The question arises, How does the galvanic current act? In order to decide this the same experiments with direct faradization related in the above mentioned paper were now executed with direct gastro-galvanization on healthy and sick people.

The method consisted in examining each individual, first when fasting, by means of a stomach-tube, in order to ascertain whether the stomach was empty or not; the contents occasionally found there were removed. Then each one of them drank 100 c.c. of water and swallowed the electrode, electricity, however, not being applied. After ten minutes the electrode was withdrawn, and the stomach contents withdrawn by means of a tube, and examined to determine the amount of hydrochloric acid and the degree of acidity. After this the subject drank again the same quantity of water, and the stomach was now galvanized (the deglutable electrode being in the stomach, the other beneath the processus ensiformis on the epigastrium), the strength of the current being always about fifteen milliampères, very seldom twenty; the duration of the application was ten minutes; the current was applied constantly without any interruption whatever.

After the galvanization the contents of the stomach were obtained, examined, and compared with the first portions. The influence of the positive and negative poles upon the stomach in reference to the secretion of juice was also determined. In several trials comparative examinations were made on the same individual as to the effect of the galvanic and faradic currents on the secretion of gastric juice. The experiments made for this purpose were divided into two groups:

I. The behavior of the galvanic current applied to the inner stomach wall in people without any digestive troubles.

1. F. R——, aged twenty-seven, servant. *a.* August 22, 1891.—*a.* Fasting condition; drinks 100 c.c. of water and swallows the electrode, which is left in the stomach for ten minutes. By means of a tube 95 c.c. of the stomach contents are obtained. Reaction acid; HCl = 0; acidity = 12;[1] propeptone = 0; peptone, biuret reaction + (faint); Lugol's solution remains unchanged; Uffelmann's reagent (weak solution of carbolic acid + ferr. sesquichlorat.) becomes discolored, but not to a straw-yellow; rennet ferment + (equal parts of the filtrate and milk, after fifteen minutes almost firmly coagulated, after an hour absolutely firm coagulation).

β. Drinks again 100 c.c. of water and is galvanized for ten minutes, negative pole being in the stomach. By means of a tube 85 c.c obtained. Reaction, faintly acid; HCl = 0; acidity = 6; propeptone = 0; biuret reaction +; Lugol's solution unchanged; Uffelmann's reagent discolored but not straw-yellow. In order to produce the discoloration of the U. reagent a much larger portion has to be added from *β* than from *a*; rennet ferment = 0 (?) (equal parts of filtrate and milk, after fifteen minutes unchanged; after an hour still unchanged; after six hours unchanged; on the following day coagulated in very fine, not coherent curdles).

b. August 25th.—Drinks in a fasting condition 100 c.c. of water and is galvanized for ten minutes (the negative electrode being in the stomach). 115 c.c. of a clear watery fluid mixed with a little mucus obtained: Reaction — faintly acid; HCl = 0; acidity = 2; rennet = 0.

[In this and in the following trial the control-test of swallowing the deglutable electrode without galvanization has been omitted, as it was too troublesme for Mr. F. R—— to undergo all the necessary procedures so often in succession.]

c. August 27th.—Drinks while fasting 100 c.c. of water and is galvanized for ten minutes; negative electrode in the stomach. By means of a tube 60 c.c. obtained: HCl + weak; acidity = 16; rennet +. In order to ascertain the chemical function of the stomach in this individual the contents of his stomach were examined again, one hour after a cup of tea and a roll had been partaken of: HCl +; acidity = 80. The acidity

[1] Read before the Medical Society of the County of New York, December 28 1891.

[2] New York MEDICAL RECORD, May 9, 1891.

[3] Lately I have made the electrode a little smaller than that demonstrated in the Academy meeting (see figure), and its use has become still more convenient.

[4] MEDICAL RECORD, June 13, 1891.

[1] The degree of acidity was always expressed by the amount of c.c. of a one-tenth standard sodium-hydrate solution necessary to neutralize 100 c.c. of the filtrate.

found was higher than normal; but whether this was the result of the several experiments made on the stomach of F. R—— during the latter part of August, or whether his stomach usually works this way, is hard to tell. In fact, we have no exact standard from which we could deduce that this is the normal. I think the normal varies in a certain degree with each individual. We can, however, speak of a normal standard found by averaging the majority of cases.

2. George N. I——, aged forty-five, at present free from any distress from the digestive organs.

a. October 6, 1891.—*α.* While fasting (had partaken one hour previously of a glass of water) 60 c.c. of water obtained by means of a tube: HCl +; acidity = 68. *β.* Drinks 100 c.c. of water and swallows the electrode, which is left in the stomach for ten minutes; thereupon the electrode is withdrawn, and the contents of the stomach (90 c.c.) obtained: HCl +; acidity = 10. *γ.* Drinks 100 c.c. of water and is gastro-faradized internally for ten minutes. Obtained contents = 90 c.c.: HCl +; acidity = 13.

b. October 15th.—*α.* When fasting (one hour after a glassful of water). Obtained contents about 50 c.c.: HCl +; acidity = 22. *β.* Drinks 100 c.c. of water and swallows the electrode, which is left in the stomach for ten minutes. Obtained contents = 80 c.c.: HCl = 0; acidity = 4. *γ.* Drinks 100 c.c. and is galvanized for ten minutes (negative pole in the stomach). Obtained contents = 130 c.c.: HCl = 0; acidity = 2.

3. Rose N——, about twenty-seven years of age, being in perfect health, servant.

a. August 11, 1891.—Drinks when fasting 100 c.c. of water and is galvanized for ten minutes (negative pole being in the stomach). By means of a tube 120 c.c. of the contents are obtained: reaction, slightly acid; HCl = 0; acidity = 4; rennet ferment = 0.

b. August 12th.—Drinks, when fasting, 100 c.c. of water and is galvanized for ten minutes (positive pole in the stomach). By means of a tube only 30 c.c. of a yellowish fluid are obtained: reaction, slightly alkaline; rennet ferment = 0; a slice of hard-boiled egg albumin put into this liquid is digested in three hours. Here the greater part of the water seems to have already disappeared from the stomach, either by resorption, or by finding its way to the small intestines; the obtained contents consisted mainly of the bile and duodenal secretion, as shown by the reactions described.]

c. August 25th.—Drinks while fasting 100 c.c. of water and is gastro-faradized internally for ten minutes. Only 40 c.c. could be obtained: reaction, slightly acid; HCl = 0; acidity = 4; Rennet ferment = 0. The circumstance that after the internal gastro-faradization no HCl had been found in the contents of the stomach caused me to examine the chemical function of the stomach one hour after Ewald's test-breakfast.

November 7th.—One hour after breakfast: HCl = 0; acidity = 24; rennet +.

In this way it seems quite apparent that the last person, although in perfect health, did not furnish a normal chemical condition of the stomach; therefore the results obtained by direct electrization in this case cannot be of any value for the purposes in question. This case, however, is interesting in as far as it shows that, notwithstanding such anomaly in the secretion of the stomach (absence of free hydrochloric acid and very low acidity), a person can be in perfect health.

In a fourth perfectly healthy individual the same experiments in reference to the efficacy of internal gastro-electrization were made. But very little of the stomach contents could be obtained, even after several trials; the person had to make use of abdominal pressure quite a long time and with force. These results are, according to my opinion, unfit to be made use of, for the reason that the irritation from the tube during strained expressure undoubtedly caused a certain amount of gastric juice to be secreted; therefore I think it preferable to omit the experiments referring to this individual.

II. The behavior of the galvanic current applied to the internal stomach-wall in those with digestive troubles.

1. Theodore S——, forty-seven years of age, suffering with dilatation of the stomach with hyperacidity.

a. September 29, 1891.—When fasting the stomach was found to be empty. *α.* Drinks 100 c.c. of water and swallows the electrode which is left in the stomach for ten minutes. 50 c.c. of the contents: HCl +; acidity = 12. *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (negative pole in the stomach). 70 c.c. obtained: HCl = 0; acidity = 5.

b. September 30th.—When fasting, stomach empty. *α.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes, the contents obtained = 30 c.c.: HCl +; acidity = 16. *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (positive pole in the stomach). 150 c.c. obtained: HCl +; acidity = 16.

c. October 1st.—When fasting, stomach empty. *α.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes the contents obtained = 70 c.c.: HCl +; acidity = 18. *β.* Drinks 100 c.c. of water and is faradized for ten minutes. Obtained 70 c.c.: HCl +; acidity = 18.

2. Jacob M——, twenty-four years of age. Diagnosis: Anæmia, dilatation of the stomach, hyperacidity, enlarged spleen in consequence of previous malaria.

a. October 13th.—When fasting the stomach contains 20 to 30 c.c. of a viscid, opalescent, turbid fluid, of a slightly alkaline reaction. *α.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes, contents obtained = 100 c.c.: HCl + (traces); acidity = 10. *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (negative pole in the stomach). Obtained 120 c.c.: HCl = 0; acidity = 12.

b. October 16th.—When fasting, only 5 c.c. withdrawn, the reaction being slightly alkaline. *α.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes obtained 115 c.c. (about 15 c.c. of mucus): HCl + (traces); acidity = 12; rennet ferment +. *β.* Drinks 100 c.c. of water and is gastro-faradized internally for ten minutes. Obtained 100 c.c. (about 15 c.c. of mucus): HCl + (well marked); acidity = 14; rennet +.

c November 5th.—When fasting, only a few c.c. found in the stomach with HCl = 0; reaction, weakly acid. *α.* Drinks 100 c.c of water and is galvanized for ten minutes (negative pole in the stomach). Obtained 40 c.c.: HCl = 0; acidity = 2; rennet ferment coagulation after one hour.

d. November 8, 1891.—When fasting, about 20 c.c.: HCl +. *α.* Drinks 100 c.c. of water and is galvanized (positive pole in the stomach). Obtained 60 c.c.: HCl +; acidity = 24. *β.* Drinks 100 c.c. of water and is faradized directly for ten minutes. Obtained 120 c.c.; the fluid turns green after standing a little while; this indicates an admixture of bile: HCl +; acidity = 24.

3. Aaron W——, thirty-three years of age; dilatation of the stomach, hyperacidity.

a. November 14th.—When fasting, about 20 c.c.: reaction acid; HCl = 0. *α.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes the contents obtained = 100 c.c. (with a greenish color of admixed bile): HCl +; acidity = 20.[1] *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (negative pole in the stomach). Obtained 50 c.c.: HCl +; acidity = 20.

b. November 27th.—When fasting, 20 c.c.: reaction, very faintly acid; HCl = 0. *α.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes, obtained 95 c.c.: HCl = 0; acidity = 4. *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (negative pole in the stomach). Obtained 60 c.c.: HCl + (traces); acidity = 16.

[1] The degree of acidity of the contents must have been lessened by the admixture of the bile, and would have been higher otherwise.

c. November 27th.—When fasting, 10 c.c. : HCl +. *a.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes obtained 100 c.c. : HCl + (traces); acidity = 10. *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (negative pole in the stomach). Obtained 100 cc. : HCl + (traces); acidity = 10.

d. November 30th.—When fasting, 25 c.c. stomach-juice : HCl +. *a.* Drinks 100 c.c. of water and swallows the electrode. After ten minutes, obtained 70 c.c. : HCl + ; acidity = 18. *β.* Drinks 100 c.c. of water and is galvanized for ten minutes (negative pole in the stomach). Obtained 100 c.c. : HCl + ; acidity = 32.

The following table shows the results of all the trials just described :

rent applied directly to the stomach produces a secretion of hydrochloric acid (no difference being noticed whether the positive or negative pole be in the stomach). The reason for the divergence of opinion might perhaps be found in the circumstance that Jones made use in his experiments of the Stockton electrode, which, in the same way as the ordinary stomach-tube, must act as a potent irritant on the stomach wall. Jones states, however, that he did not find any hydrochloric acid in his control experiments.

Whereas the faradic current in these experiments seems to augment the gastric secretion, the galvanic current appears rather to exert a slightly diminishing action in the production of gastric juice, especially when the negative

From the above-mentioned table it seems that direct galvanization of the stomach—the negative pole being within this organ—does not heighten the secretion of gastric juice ; it seems rather to have a tendency to diminish the degree of acidity in healthy as well as in those with stomach troubles ; *i.e.*, the presence of the electrode in the stomach without galvanization produces in a given time more gastric secretion (or rather acid) than the presence of the electrode combined with galvanization (negative pole in the stomach). This, however, was not the case in the patient Aaron W—— (Table II., 8 and 10), where an increase of acidity was twice observed. The experiments made with galvanization, the positive pole being in the stomach, were very few, and once the degree of acidity was found equal to that in the control experiment (Table II., 2). At another time the patient was examined, first with the negative pole in the stomach, then with the positive pole in the stomach (Table II., 6) ; here the acidity was higher when the positive pole was in the stomach than when the negative pole was there ; but there was no control experiment made.

These experiments with direct galvanization are not numerous enough to allow any positive conclusions to be drawn and will have to be completed in the future.

The figures obtained, however, are not in accordance with the views of Allen E. Jones,[1] that the constant current applied directly to the stomach produces a secretion of hydrochloric acid (no difference being noticed whether the positive or negative pole be in the stomach). The reason for the divergence of opinion might perhaps be found in the circumstance that Jones made use in his experiments of the Stockton electrode, which, in the same way as the ordinary stomach-tube, must act as a potent irritant on the stomach wall. Jones states, however, that he did not find any hydrochloric acid in his control experiments.

[1] Jones, loc. cit.

Whereas the faradic current in these experiments seems to augment the gastric secretion, the galvanic current appears rather to exert a slightly diminishing action in the production of gastric juice, especially when the negative pole is in the stomach. Should we wish to utilize therapeutically these experimentally obtained conclusions, we would expect theoretically that the faradic current would be more advisable in cases of subacidity, whereas the galvanic current would be preferable in cases of hyperacidity. But in reality we shall see later on that this cannot be made an axiom for the therapeusis. There were cases of hyperacidity which greatly improved by the faradic treatment, and on the other hand there were cases with subacidity in which the faradic current did not bring much benefit and the galvanic current proved very useful.

My above-mentioned experiments are all made for the purpose of seeing what electricity does right away, *i.e.*, during the electrization itself. It will certainly be important to determine what the stomach does a little while after the electrization. Experiments relating to this point I shall make later on.

After this long deviation I would like to return to my proposed subject, namely, to the therapeutic efficacy of direct electrization of the stomach.

A. **Direct Faradization of the Stomach.**—As stated in my last paper,[1] direct gastro-faradization has been applied from time to time by several authors, although quite seldom. There is very little literature to be found in regard to this subject. I highly appreciate the work of

[1] M. Einhorn, MEDICAL RECORD, loc. cit.

Charles G. Stockton,[1] who applied direct gastro-faradization in a great number of cases (dilatation of the stomach and many functional disturbances of this organ going along with hyperacidity and also subacidity), and warmly recommended this method of treatment. In his elaborate paper Stockton, trying to give an explanation for the efficacy of electrization, says:

"Exactly what rôle is played by faradization I am unable to state; whether it is a gastric sedative or a gastric stimulant I do not know. My efforts were in the direction of study, and the results were so favorable that I applied faradism to cases seemingly contradictory in character, and I have concluded that the great variety of gastric neuroses depend upon a common cause—an imperfect innervation of the stomach; that electricity improves this innervation, thereby relieving the cause and so the conditions which, at first th ught, are so contradictory."

As the subject of direct gastro-faradization is quite new and very important in practice, I do not think it superfluous to describe and fully discuss a sufficient number of cases representing the various types of stomach diseases treated by this method.

In all my cases the deglutable electrode was made use of and the method of application was the same as I gave it in the above-mentioned paper.

From June, 1890, to November, 1891, I have had the opportunity of undertaking this mode of treatment by direct gastro-faradization in 29 patients. The same may be classified as regards their diseases as follows: Hyperacidity combined with dilatation of the stomach, 12 (among these, three with severe gastralgia and one with continuous hypersecretion); gastroxynsis, 1; belching, atony of the cardia, 3; chronic gastric catarrh (gastritis glandularis chronica), 4; chronic gastric catarrh with beginning atrophy of the mucous membrane of the stomach, 3; anadenia ventriculi (atrophy of the mucous membrane of the stomach), 1; severe gastralgia, 5; (one among them with gastro succorrhœa continua chronica).

1. *Hyperacidity.*—March 12, 1891.—H. J. F——, thirty-three years of age, merchant, suffered for about three years from pains after meals. For several months the distress after eating increased to such an extent that the patient was forced to (spontaneously) produce vomiting after each meal, in order to obtain some relief in this way. The appetite was very poor. The examination showed the lower border of the stomach situated midway between the umbilicus and the symphysis.

March 13th.—The examination of the stomach contents one hour after the test breakfast shows: HCl +; acidity = 96. Diagnosis: Dilatation of the stomach, hyperacidity, and gastralgia. Besides the usual treatment with alkalies the patient was gastro-faradized internally. After the third electric séance the patient noticed that the pains had grown less and that he ate with good appetite on the days when electricity was applied. In about a month's time (at the beginning of April) the condition of the patient had been ameliorated to such a degree that he had no pains and could enjoy his meals thoroughly. According to a letter which he sent me on October 24, 1891, he had been free from pains and enjoyed good health since the time of the electrical treatment.

2. August 15, 1890.—Julius K——, aged thirty-six, laborer; suffered for about three years from obstinate constipation; with this he has headaches and a sensation of fulness in the stomach. No vomiting. There is constant repeating, sometimes of water, in such a way that the patient's throat has become roughened by it. He has lost forty-five pounds in weight. Examination shows the lower border of the stomach situated two to three fingers' width below the navel. When fasting, gastric juice is present in the stomach.

September 16th.—When fasting, the stomach contains 60 c.c. of juice: HCl +; acidity = 90.

September 18th.—One hour after test-breakfast: HCl +; acidity = 100. Diagnosis: Gastrosuccorrhœa continua chronica; hyperacidity; dilatation. Therapy: magnes. ust., pulv. rhei, āā 7.5; sodii bicarb., sacch. lact., āā 25.0. One teaspoonful three times a day; washing of the stomach.

After this treatment, chiefly with alkalies, the condition of the patient was ameliorated, but there remained the feeling of fulness. Gastro-faradization was applied internally twice a week for about two months (August and September, 1890). After a few sittings the patient asserts that he feels much easier; he gains in weight and the distress after meals does not manifest itself. The objective examination shows, however, that there is still hyperacidity and hypersecretion, although in a less degree.

3. T. F. H——, thirty years of age, merchant; has digestive troubles of several years' standing; there is loss of appetite, very frequent repeating; pains from time to time; feeling of fulness after meals; constipation.

The examination reveals: lower border of the stomach three to four fingers' width below the navel (gastrodiaphany); here splashing can be elicited. One hour after test-breakfast: HCl +; acidity = 120.

Therapy: Alkalies and direct gastric-faradization (April 1 to 26, 1891). After a few days of this treatment the condition of the patient becomes ameliorated; he enjoys his meals; bowels regular; repeating lessened. April 26th the patient asserts that he is free from any trouble whatsoever.

Eight other cases so much resemble the three cases just described, as regards the symptoms as well as the treatment and the influence of faradization, that I may be allowed to abstain from giving a full record of them.

II. *Gastroxynsis* (Rossbach).—August 31, 1890.—George N. J——, forty-two years of age, merchant, suffered for five years from frequently appearing attacks of pains in the region of the stomach; these attacks were usually accompanied by vomiting of highly acid substances; they recurred once every three to four weeks and lasted about three days. During the attack the patient felt miserable and down-hearted, suffered from severe pains; was not able to eat anything and vomited frequently. When the attack was over the patient felt perfectly well, except that his sleep was somewhat disturbed. The physical examination shows: Chest and abdominal organs intact; the patellar reflex present; stomach not dilated (the site of the stomach having been determined by gastrodiaphany).

August 31, 1891.—One hour after test-breakfast, HCl +; acidity = 66. Diagnosis: Gastroxynsis (Rossbach).

Treatment: The patient was directly gastro-faradized every other day during September, and twice a week during October, 1891. He had no attack during the time of treatment, nor any thus far after the treatment; sleeps well, and feels stronger and full of life.

III. *Repeating.*—Repeating is a symptom which occasionally appears and accompanies the most various disturbances of the stomach-function. Here, however, a few cases might be described in which this symptom was the main complaint and overshadowed all other distress.

1. October 7, 1890.—Henry L——, forty years of age, suffered several years from frequent repeating; during the last year the repeating increased to such a degree that the patient was partly unable to attend to his business; besides this, he had for several months the sensation of fulness after meals and a tired feeling; appetite pretty fair; bowels somewhat constipated. Status præsens: chest intact; the palpation of the abdomen reveals splashing sounds in the gastric region; these sounds can be produced and heard down to a point two fingers above the navel.

October 10, 1890.—One hour after a test breakfast: HCl +; acidity = 80.

Diagnosis: Hyperacidity and atony of the cardia.

Treatment: Alkalies and direct gastro-faradization twice to three times every week.

[1] Clinical Results of Gastric Faradization, American Journal of the Medical Sciences, 1890, p. 20.

After a few sittings the patient felt better, and on November 6, 1890, the electrical treatment was discontinued. The patient said several months afterward that he had not been troubled any more from repeating after the discontinuation of the electricity.

June 4, 1891.—The patient called on me again, complaining of distress in his stomach in consequence of an acute indigestion; the appetite was lessened and the repeating had partly returned. The patient was directly gastro-faradized twice a week from June 4th to June 19th and thereafter only once a week until July 27th. The distress of the patient, especially the repeating, disappeared during the first fortnight's treatment; the electricity was applied, however, a little longer as a means of precaution. Since that time the patient has been free from his complaints.

2. Miss Emma M——, twenty-four years of age, suffered for three years from loss of appetite, repeating, constipation, and poor sleep; there was no vomiting but repeating of acid fluid after meals. One of the worst complaints of the patient was of this highly annoying ructus, which never left her, and in consequence of which she was retarded in her occupation and frequently kept away from society.

April 1, 1891.—Status præsens: Tongue thickly coated; splashing sound from the stomach to a point two fingers' breadth below the navel; the right kidney is clearly palpable and easily moved. Examination of the stomach in the fasting condition by means of a tube shows that there is bile mixed with gastric juice in the stomach; also after the trial breakfast the contents of the stomach were usually found mixed with bile, as will be seen from the following memorandum:

April 3d.—One hour after the trial breakfast: HCl + ; acidity = 68 ; admixture of bile.

April 5th.—When fasting, the stomach contains 70 cc. of an intensely yellow-colored fluid (bile present): HCl +.

Diagnosis: Enteroptosis; acidity only slightly increased, hypersecretion; relaxation (atony) of the cardia and the pylorus.

The treatment consisted in direct gastro-faradization and once in a while washing of the stomach. During the month of April the faradization was applied every other day, and the lavage of the stomach once a week in the fasting condition. On these occasions, before the washings, the stomach was examined each time in regard to its contents; during April each examination revealed the presence of quite a large amount of bile mixed with gastric juice in the stomach when fasting. Later on the amount of fluid found when fasting gradually decreased, and during June the stomach was found to be either empty or there were occasionally a few cubic centimetres of gastric juice, but without the admixture of bile. The patient felt better after a few days' treatment; the repeating disappeared almost entirely at the end of April, and she could eat with good appetite, having no distress afterward.

During June and July the faradization had been applied once a week and thereupon stopped entirely. The patient gained several pounds during treatment, and has been pretty free from complaints since that time.

3. Mrs. H. G——, about forty three years of age, complained for several years of a feeling of fulness, poor appetite, and frequent repeating. Whereas all the other digestive inconveniences manifest themselves for a longer period of time, the repeating never ceases entirely, and annoys the patient more than the other symptoms.

Status præsens: Patient looks well-nourished and of a healthy color; tongue slightly coated; chest normal; palpation of the abdomen does not reveal anything abnormal, except, perhaps, a certain sensitiveness on pressure over the gastric and epigastric regions. One hour after the test breakfast: HCl + ; acidity = 50 ; lactic acid +. The stomach contents mixed with much mucus.

Diagnosis: Gastritis glandularis chronica; atony of the cardia.

The treatment consisted of the administration of nux vomica and direct gastro-faradization, at first every other day, and thereafter twice a week from September 16 to October 23, 1891. After a week's treatment considerable amelioration was noticeable, inasmuch as the appetite had improved and the repeating decreased. October 13th the patient had no complaints from the digestive apparatus and the repeating had disappeared almost entirely. The tongue was clean and the examination of the stomach contents one hour after the test-breakfast showed: HCl + ; acidity = 60 ; lactic acid not present; the amount of mucus very slight.

IV. *Chronic Gastric Catarrh* (*Gastritis Glandularis Chronica*).—Besides the last case of chronic gastric catarrh mentioned under the sub heading "Repeating," four cases of this sickness were treated by direct gastro-faradization.

One of these cases was Captain L. M——, suffering from neurasthenia and chronic gastric catarrh, accompanied by dilatation. Here the direct gastro-faradization had been administered for about a month, but without any benefit whatever; all the symptoms continued just as before. The other three cases resembled each other very much and the report of one of them will be sufficient as an illustration.

September 18, 1891.—Mrs. L. W——, about twenty-six years of age, suffered for about four years from frequently recurring digestive disturbances (poor appetite, pains in the region of the stomach and in the abdomen); she had been treated by several competent physicians, sometimes with good results. During the last summer the general health of the patient was impaired; the complaints, however, greatly increased during the past six weeks; there appeared pains in the region of the stomach, the patient could not eat sufficiently, for soon after partaking of the food she had a sensation of being laced; she could not sleep, and suffered much from repeating and flatus; during the summer she lost in weight considerably.

Status præsens: Patient has a pale appearance and frail structure; color of lips and cheeks pale; tongue coated; chest organs normal; abdominal wall relaxed; the abdomen slightly distended; the epigastric region somewhat painful on pressure; the splashing sound can be produced below the left margin of the ribs down to a point three fingers' width above the navel.

September 19th.—One hour after the test-breakfast: HCl = 0; lactic acid + ; acidity = 60 ; erythrodextrin + much; mucus present.

September 22d.—When fasting, stomach is found empty; lavage brings up very little mucus.

Diagnosis: Gastritis glandularis chronica.

Treatment: Nux vomica, HCl, gymnastics, cold washing and rubbing of the body, and direct gastro-faradization, the first fortnight every other day and thereafter twice a week (the faradization was applied from September 23, to October 20, 1891).

Soon after the beginning of this treatment the patient felt better; she could partake of more food; the pains first decreased in severity, and soon disappeared almost entirely. The patient gained during treatment (six to seven pounds) and obtained a good and healthy color.

October 1st.—The examination of the stomach contents one hour after breakfast showed: HCl + ; lactic acid = 0 ; acidity = 56. The muriatic acid was discontinued, and arsenic and iron given instead.

October 23d.—The examination of the stomach contents one hour after the test-breakfast showed: HCl + ; lactic acid not present; acidity = 60. Notwithstanding there were now no complaints from the stomach, the patient had once in a while (once in from five to seven days) a pain appearing at a place located two fingers' width below the lower margin of the left ribs, and lasting for about half an hour. In order to combat this the galvanic

current had been applied, negative pole in the stomach, the positive electrode at the painful spot. November 2d, the patient asserted that the pain appeared only once after galvanization and was very mild.

(To be continued.)

REPORT OF ONE HUNDRED AND THIRTY-SIX CASES OF CATARACT EXTRACTION, WITH REMARKS.[1]

By DAVID WEBSTER, M.D.,

NEW YORK.

I REPORTED thirty-five cases of cataract extraction to this Society at its Nineteenth Annual Meeting, and again, in July, 1886, I reported an additional fifty cases. Since that time I have operated upon one hundred and thirty-six eyes with uncomplicated cataract, in private and in hospital practice. Twenty of these eyes were operated upon by the method then most common, von Graefe's method modified; the remaining one hundred and sixteen by the simple method.

In performing the simple extraction, I have commonly used a speculum and fixation forceps. In most cases the speculum was not removed until the operation was finished; in some cases it was removed as soon as the cut was made, and in a few cases no speculum was used at all, the lids being held open by an assistant. At present my feeling is in favor of removing the speculum on finishing the section. It seems to me that by so doing we may sometimes avoid the loss of vitreous that comes from sudden spasmodic squeezing of the eye with the speculum in it. I make my cut upward, with the Graefe knife, large enough to include a little less than half of the circumference of the cornea, all the way in the limbus or semi-transparent cornea, and completing it so as to make a slight conjunctival flap, if possible. In some cases I have had to turn the edge of my knife forward so as to avoid wounding the iris, and so brought the apex of the cut out in the clear cornea. I dislike such a complication, as it is very likely to be followed by grooving of the wound and delayed healing, with a good deal of irritation of the eye. But it seems preferable to mutilation of the iris.

In lacerating the capsule, I have tried to avoid injuring the iris. I have endeavored to make the opening in the capsule at the lower border of the pupil, thinking that in this way a secondary operation might sometimes be avoided. I have usually expelled the lens by pressure on the lower border of the cornea with a tortoise-shell spoon, though sometimes I have used only pressure with my thumb upon the lower eyelid. I have in no case attempted to syringe out the remaining cortical matter. What I have failed to remove by manipulation has remained in the eye, and I am not sure that it has, in any case, given rise to bad results. It simply delays the restoration of good vision. In cases in which the iris remained in the wound after the removal of the lens was accomplished, I have endeavored to replace it by gently rubbing the upper lid of the closed eye. Where that would not restore it to its normal position, I have pushed it back with a rubber spatula. I have endeavored, in all cases, to leave the pupil clear, central, and circular.

All, or nearly all, the operations were done under cocaine, and of this a sterilized four per cent. solution was dropped into the eye three or four times. I like to have the cocaine dropped into the eye long enough beforehand, so that the pupil may be slightly dilated when the operation is commenced. Fifteen or twenty minutes will be sufficient. Immediately before operating, I have washed the eyelids, inside and out, with Panas's fluid, using it very freely. All the instruments used are carefully cleansed in boiling water, before and after the operation. The hands of the operator and of his assistants are washed with soap and water, and the finger nails scrupulously cleansed.

[1] Read before the American Ophthalmological Society, on September 23, 1891.

Before dressing the eye, immediately after the extraction I first instil a drop of solution of eserine, gr. j. ad ℥j. I then apply a little white vaseline to the edges of the lids to keep them from sticking together. I then apply a prepared wad of absorbent cotton over both eyes, and over that a roller bandage of the thinnest flannel. Over the flannel bandage I apply a parallelogram of black silk lined with cotton, and with a tape at each corner, so as to make a four-tailed bandage, tied so that the knots will be at the side of the head. I let my patient sit up from the first if he desires to. Unless the patient complains of pain in the eye, or that the bandage is too tight or in other respects uncomfortable, I do not remove it until about forty hours after the operation. If the eye is doing well, and the wound has healed, after washing both eyes, I apply clean cotton compresses, and again tie on the black silk dressing, leaving off the roller bandage. If the anterior chamber is still empty, I reapply the whole dressing as at first. In favorable cases both eyes are kept tied up for from five to ten days. Then the cotton is left off and the lower strings of the black silk dressing cut off, so that it becomes simply a shade hanging down over the eyes. I think it important that both eyes should be kept tied up until the wound has become thoroughly healed, for if one is left uncovered it will roll about, and the wounded eye will roll about with it, and the healing will thus be delayed.

On about the fifteenth day, or as soon as the eyes seem strong enough, the shade is removed and medium smoke coquille glasses substituted. I like to defer fitting the patient with glasses until all redness has passed off from the eye.

Visual Results.—Of my 20 cases of extraction by von Graefe's method the resulting vision was as follows: In 1 eye vision was $\frac{20}{20}$; in 2 eyes, $\frac{20}{40}$; in 1 eye, $\frac{20}{50}$; in 1 eye, $\frac{20}{70}$; in 1 eye, $\frac{20}{100}$, in 9 eyes, $\frac{20}{200}$; in 1 eye, $\frac{15}{200}$; in 1 eye, $\frac{10}{200}$; in one eye, counting fingers; in 1 eye, perception of light; in 1 eye, 0.

According to the commonly accepted standard this would give: Successes, 15, or seventy-five per cent.; partial successes, 3, or fifteen per cent.; failures, 2, or ten per cent. Upon twelve of these eyes no secondary operation was performed. Five of them had one keratonyxis each. Two of them had two needlings each. One of them had two needlings and an Agnew's hook operation.

The patient whose final vision was ability to count fingers had vision = $\frac{20}{50}$ following a keratonyxis done thirty days after the extraction. A second needling was done about three and a half months later, and was followed by increased tension. Under the use of eserine the vision came up to $\frac{18}{200}$. Three weeks later a membrane was removed from the pupillary area by means of a sharp hook. The immediate result seems not to have been noted, but my recollection is that the sight of that eye was good until nine months later, when an attack of acute glaucoma was developed during recovery from an extraction of the cataract from the other eye, and vision was reduced to counting fingers.

The case resulting in perception of light only, lost the eye by plastic iritis, or irido-cyclitis, resulting in closure of the pupil and anterior atrophy. The patient whose vision was *nil* was an unruly man, who tore off his bandages as often as they were replaced, and who finally died of meningitis, the result of panophthalmitis, eighteen days after the operation.

Of my 116 cases of simple extraction the resulting vision was as follows: In 11 eyes, vision was $\frac{20}{15}$; in 15 eyes, $\frac{20}{20}$; in 23 eyes, $\frac{20}{30}$; in 24 eyes, $\frac{20}{40}$; in 13 eyes, $\frac{20}{50}$; in 11 eyes, $\frac{20}{70}$; in 4 eyes, $\frac{20}{100}$; in 5 eyes, $\frac{20}{200}$; in 1 eye, $\frac{18}{200}$; in 1 eye, $\frac{15}{200}$; in 2 eyes, $\frac{10}{200}$; in 1 eye, $\frac{5}{200}$; in 1 eye, "sees objects;" in 1 eye, "perception of light;" in 1 eye, 0; in 2 eyes, not noted.

There were, then, 106 eyes that had vision of $\frac{20}{200}$ and better, or, successes, ninety-one per cent.; 6 eyes that had vision from $\frac{18}{200}$ to seeing objects, or partial successes, five per cent.; and 4 eyes that had vision "perception of light," or 0, or three per cent. failures.

The case noted as resulting in "perception of light," was one in which suppurative iritis set in, beginning at the wound, which was cauterized without arresting the disease. Closure of the pupil and a soft eyeball resulted, so that any further operation seemed out of the question.

The case in which vision is noted as nil had one eye operated upon previously with excellent result. The eye that was lost did well up to the fifth day, when the wound was entirely healed, the pupil central, circular, and black, and the eye looking so well that the dressing was left off and only the black shade applied. The next day there was a good deal of redness of the eye, with secretion, and on the following day well-marked purulent ophthalmia had set in, which resulted in total loss of vision.

In one of the cases in which the vision was not noted we find a history of violent insanity setting in on the day after the operation, and the patient had to be sent away from the hospital on the third day. For aught that I know she may have recovered with a good eye, but on the whole I thought it best to class her case with the failures. In the other case there was prolapse of the iris. This was excised, and the hospital history says she steadily improved, and she went home on the sixteenth day and there are no further notes of her case; so I put her also with the failures.[1]

Prolapse of iris occurred and had to be excised in 5 cases out of the 116, or in four per cent. The actual cautery was applied in 2 cases, in 1 of prolapsed iris where excision proved to be insufficient, and in 1 case where suppuration of the wound occurred. Needling of secondary membranes in the pupil was performed in 50 cases, or in forty-three per cent. of all the cases. Agnew's hook operation was resorted to in 3 cases in which needling had failed. Paracentesis was done in 1 case in which increased tension had developed itself. The eye recovered with good vision.

As to accidents during the operation, in 2 cases the iris fell before the knife and was wounded in cutting out.

In 6 cases there was loss of vitreous. In 2 of these cases the lens became dislocated, and on making pressure in the usual way the vitreous presented at the wound instead of the lens. The wire spoon was then introduced and the lens withdrawn with loss of vitreous. In 1 case the patient squeezed his eye and expelled the lens in its capsule with vitreous *per saltum*. In the other 3 cases the vitreous followed the lens while it was being pressed out in the usual way, the patient losing control and contracting his orbicularis spasmodically.

I usually instil a drop of a one per cent. solution of atropine on the third or fourth day after the extraction, experience having shown that even in cases where there is no apparent iritis, sufficient bruising of the iris may have occurred to produce adhesions to the capsule.

As to the management of prolapse of the iris occurring during recovery from the simple extraction, my experience strongly biases me in favor of early excision. I have watched the prolapse in several cases, and have seen it increase day after day, the eye at the same time becoming more and more irritable until the prolapsed iris was excised, and in such cases I have regretted that I had not cut it off when it first appeared. I once replaced it with the spatula, but it had reappeared as large as ever when the eye was next opened, and had to be excised in the end.

It is safer to give ether for excision of prolapsed iris, as cocaine generally proves insufficient to make the operation painless, and the patient is apt to move the eye suddenly as soon as the iris is seized by the forceps, and before the scissors can be used. When cut off with the scissors without traction with the iris forceps, some iris is commonly left in the wound, and the eye heals with synechia anterior.

[1] This patient returned to the hospital and an iridectomy was performed on the eye, and on November 27th her vision was $\frac{3}{200}$, thus taking her case out of the losses and placing it with the partial successes.

THE NECESSITY FOR EARLY MECHANICAL TREATMENT IN INFANTILE SPINAL PARALYSIS.[1]

By W. R. TOWNSEND, A.M., M.D,

NEW YORK.

Gowers, in his "Diseases of the Nervous System," after having sketched the symptoms of infantile spinal paralysis, or, as he calls it, atrophic spinal paralysis, says that the disease may be divided into four stages:

1. An initial stage of paralysis, rapidly increasing, often accompanied with fever; the duration of this stage is from a few hours to a week.

2. A stationary period, which lasts from a week to a month.

3. A stage of "regression," during which the palsy passes away, except from certain parts in which wasting occurs. This regressive period usually occupies from one to six months.

4. A chronic stage, during which the atrophy continues; slight improvement may occur, but contractures and deformities are developed. The duration of this stage is indefinite. Improvement often occurs after three, six, or twelve months, but is then usually slight, and often more than counterbalanced by the interference with growth and by the occurrence of deformities.

This last or fourth stage is the time when the cases are usually seen by the orthopedic surgeon, but a careful study of the symptoms shows that much might be accomplished if the cases were seen earlier, and that the fourth stage, although it could not be prevented, would be much changed, and the deformities and contractures might be avoided, or at least much diminished. We know that in nearly all cases the paralysis at first is extreme, yet the large majority recover, the amount of power that is regained varying in different cases; and it thus becomes an important question to decide as early as possible how much motion will be recovered. During the febrile attack neurologists tell us that no positive information can be given, but that by the end of the first week usually, by several careful electrical examinations we may construct a "prognostic line." In the *American Journal of the Medical Sciences* for October, 1891, in an article on "The Responses to the Alternating Galvanic Current in Normal and Degenerate Muscles," by M. A. Starr and Charles L. Young, such a line has been worked out in the case reported. Mr. Young says: "We, moreover, think that we are justified in assuming that if, with a given current, a healthy muscle will respond to a rate of alternation which will not affect a degenerated one, an increase in the rate to which the degenerated muscle will respond shows increased susceptibility in that muscle, and a tendency to approach, in some way, the condition of a healthy one."

Duchenne first showed that the muscles in which faradic reaction remained, recovered, and Starr, in "Familiar Forms of Nervous Disease," quotes a case in which the left leg was at first totally paralyzed, but the faradic reaction did not disappear in any muscle except the tibialis anticus. After four weeks it returned in that muscle, and at the end of one year all muscles except the tibialis anticus had regained their natural size and power, and after two years the recovery was perfect in the entire limb. In the muscles which present at the end of six weeks the reaction of degeneration perfect recovery is very rare.

With this information supplied us, if it is clearly shown that the paralysis will be more or less complete, it then becomes our duty to guard against the deformities which are sure to follow.

All writers recognize the necessity of mechanical treatment in the later stages of the disease, and various operations are resorted to to correct deformities; but Bradford and Lovet, in their work on "Orthopedic Surgery," are the only authors I know of who have advised that "pro-

[1] Read before the Orthopedic Section of the New York Academy of Medicine, October 16, 1891.

tective treatment" be instituted at once, that the limbs be kept in normal position, so that the affected muscles and joints may be supported, and troublesome deformities avoided.

The deformities are usually due to two causes, trophic changes in the limbs, and muscular paralysis of one set of muscles, permitting the opposing set to contract and thus change the normal relations of the limb.

The deformities due to trophic changes are of considerable interest, but rarely demand much treatment. Starr, in "Familiar Forms of Nervous Disease," stated that in those cases where the growth of bone is affected the lesion lies deep in the gray matter, nearer to the central canal than in other cases. This may be correct, but in fifty cases, seen from two to sixty-one years after the onset of the infantile paralysis, which I have very carefully measured, in only two instances were the limbs exactly of the same length. They vary from ¼ to 3 inches. I hope to discuss this subject more fully in another paper, so will not enter into the details.

This asymmetry produces in some cases a lateral deviation of the spinal column, but as the most shortening usually occurs in the cases having the least power, they are unable to walk well if extra weight is added to the foot either by a patten or cork sole. In cases where the lower extremity is shortened the foot is also always smaller than its fellow, the shortening in many cases being very marked.

The deformities due to paralysis concern us the most, and vary very greatly. The theory that they are caused by unopposed muscular action was opposed by Volkmann, who believed that in cases of equinus, for instance, the force of gravity on the foot was the determining cause of the deformity. Both theories are no doubt partly correct. The deformities occur usually on the flexor side of the limb, and one reason for this in the lower extremity is that the extensors are more often affected than the flexors. The tibialis anticus, the peronei, and the anterior thigh muscles, when paralyzed, naturally permit the foot to be placed in equinus and the knee in flexion. Again, flexion is the position of rest and one most assumed when no special muscular effort is made. Equinus and equino varus are by far the most common varieties of paralytic club foot.

The muscles being more or less paralyzed, where they pass over joint surfaces do not exercise the same power they otherwise would, and partial luxations may occur. The ligaments, although not affected by the disease, easily become stretched, a faulty position soon becomes aggravated, the tarsal bones, owing to the deformity, acquire new bearing surfaces, false facets may appear, and the many after-effects of a club-foot, such as rotation at knee and hip, soon occur, bursæ may form, and the condition become a serious one to treat.

These after-effects do not seem to me to have been enough appreciated, although clearly set forth in the excellent monograph written by G. Hermann von Meyer, of Zurich, entitled "Der Klumpfuss und seine Folgen für das übrige Knochengerüst."

All of these difficulties may be largely overcome if we will simply bear in mind the regular progress of the disease, in the early stages use strychnia and other drugs, give electricity faithfully and for a considerable period, employ massage and manipulation and heat, and use mechanical treatment from the beginning. Do not permit the contractures to occur. Retain, in the case of the lower extremity, the foot, ankle, and knee in their proper and normal positions. See to it that as the child begins to walk, if disease come on in the first year of life, that it walks on the sole of the foot, and with foot at a right angle to the leg; this is easily accomplished by any of the simple forms of braces. If the disease come on at a later period, see that as soon as walking is resumed the foot is in proper position. If the child show a tendency to contractures before it begins to walk, put the limb up in plaster-of-Paris, a suitable brace, or fasten the limb to a cuirass or frame.

Prevention of deformity should always be our aim; the form of apparatus to be used is to be regulated by the needs of each particular case, care always being taken to as near as possible permit the unaffected muscles to act in their normal relations, and to give the palsied muscles every chance for legitimate action and stimulation. Other details of treatment need not be entered into, as they are familiar to all of us. The nutrition of the parts is also improved by proper mechanical support with muscular training, as is shown by Dr. H. L. Taylor, in his monograph on the "Hygiene of Reflex Action."

If these cases were thus systematically treated and the deformities prevented, it seems to me that possibly some of the deformities now ascribed to trophic changes might be somewhat diminished, as we know that the growth of a bone is somewhat dependent on the growth of the muscles attached to it; and in cases of club-foot, where the patient simply walks on the foot as if it were part of the lower end of the tibia and fibula, not using his extensor or flexor muscles, they certainly do not have the same chance to develop as if they acted properly; and although they may not act perfectly, yet with a proper brace, if they have any power they are so placed that they can develop.

Another point of practical interest, in these deformities due to infantile paralysis, is that in many cases the contractures come on very slowly; the patient may go for several years and then have only a slight equinus, yet that equinus, by the patient's endeavor to walk flat on the foot, may be the cause of a most severe hyperextension at the knee and much subsequent trouble.

If the case recovers power a brace can always be easily removed, and it will have done no damage while being worn; yet a failure to apply it or delay in treatment will certainly never improve the final result.

Dr. Gibney, in a paper read at the meeting of the American Neurological Association in Washington, in September, in speaking of "the supplemental treatment of the paralysis of acute anterior poliomyelitis," says that "a palsied muscle or a group of palsied muscles are often very much handicapped by contractured tendons, or muscles of the opposite side of the limb. Because of these contractures local treatment is inefficient. However efficient the galvanic or faradic current, or even massage, may be, if the muscle is overstretched this efficiency is certainly minimized—a palsied muscle or a group of palsied muscles respond better to local treatment after a period of rest, or at least after being retained for a long time in normal position. This being true, only further emphasizes the necessity for early mechanical treatment in infantile paralysis.

The Brain Jar of the Military Step.—Dr. Colin, regimental physician in the French army, has published the results of his investigations into the effects of regular marching in disciplined bodies upon soldiers. The regularity of the step causes the indefinite repetition of a shock of the bones and brain, infinitely more deleterious than an irregular walk, and to this regular repetition of the shock to the same parts of the body is due the peculiar aches, pains, and illnesses of the troops. In a one-day march, he says, this shock is repeated 40,000 times, and often the strongest men, who can walk the same distance without difficulty when not in line, succumb to the strain in two or three days. Dr. Colin's preventive is a rubber heel in all military boots. This heel has been tried at his instance in the French infantry, he says, and the result has been found to be a great relief to the soldiers. The experiments with the rubber heel are still in progress.

Opposed to Low-necked Dresses.—The mayor of Barfleur, in France, has forbidden the wearing of décolleté dresses by the women of the commune, on the ground that such costume is prejudicial to peace and social morality.

A PHYSIOLOGICAL VIEW OF CRIME.

By A. VAN HOFF GOSWEILER, A.M., M.D.,

BALTIMORE, MD.

The best methods of medical treatment and management of the insane criminal; the study of preventive measures; the medico legal relations of the insane; the great variety of interests and social problems concerned, are subjects that not a day passes but the medical superintendent for the insane is engaged in solving. A paper just issued by M. Laccassagne, on criminality in France between 1825 and 1890, contains certain information which may be profitably studied by our alienists and neurologists, if not by practitioners of general medicine. Although some of the facts differ from what occurs in this country, the principles they elucidate are the same. M. Laccassagne divides society into three layers, according to cerebral constitution, and urges medico-jurists to impress upon reformers and philanthropists the necessity of studying criminality from a physiological point of view. There is need of studying the organism and its environment. If the main conditions of a society remain the same, Quatelet shows that crimes are repeated in similar quantity and of similar kinds. It is often insisted, and in harmony with the laws of growth, that it is vastly more important to prevent a criminal from having descendants than it is to reform him. Schopenhauer had long before expressed the thought that the community of bees, for example, develop classes of members adapted to special functions, just as a body develops organs. Darwin shows that these organizations are as plastic under the great force which controls the development of life as the single organisms themselves. One society will, therefore, develop one type of character; another, another; but according to the type of character which it favors will it stand or fall.

M. Ribot, in his recent study of mental diseases after the physiological method of the new psychology, declares that the basis of the psychic individuality of every animal is the organic sense, the sense of the body, usually vague and obscure, but at times very clear to all of us, and that it exists pre-eminently in man. He believes that the organic bond of personal states of consciousness is in the organism, and makes the organism and the brain the real personality.

Crimes against property in France vary in amount with the price of food, and in the statistical table supplied by M. Laccassagne, the years of failure in agriculture show this fact. After 1860, through improved trade with England, offences against property diminished, and these have their maximum in December and their minimum in April. Crimes against persons have their minimum in November, and reach a maximum in June. The New Year's festival and gifts produce an increase of violence. Infanticide is most common in January and February. The vintage season and the carnival increase social errors that lead to these crimes and to others analogous to them. Murders are much under the influence of hot weather, and so are violent assaults and woundings. It is found that the tendency to crime is four times as strong with men as with women, but the latter commit a larger portion of crimes against those in their own circle. They use poison more frequently than men. The moral influence of women on society is evidently negative rather than positive.

The increase of town-population, the fluctuations of trade and wages, the substitution of spirits for light wines in consequence of the damage done the vineyards in certain districts of Southern France by the phylloxera, are causes of the increase of crime. With reference to criminals of low-organized, hereditary type, M. Laccassagne entertains the strange notion that they should be formed exclusively into a society; but this would only add to their degradation and form a dangerous race.

In another recent scientific study, we discover the close relation of race and climate to murder. Professor Bosco's monograph on homicide shows that, while in eight principal states in Western Europe—Spain excepted—with a population of 128,500,000 people over ten years of age, there are 2,777 annual trials for murder. Italy, with 25,000,000 individuals of like age, has 3,606 such trials. France, Belgium, England, Scotland, Ireland, Austria, Holland, Germany, with six times the population of Italy, only furnish three-fourths as many murders. The statistical tables of Dr. Bosco place the civilized nations of Europe, Scandinavia and Russia excluded, in the following ascending order of homicidal criminality: Holland, England, Germany, Scotland, France, Belgium, Ireland, Austria, Hungary, Spain, and Italy—a scale affording suggestion to the psychologist.

Hippocrates believed that all regions liable to violent changes of climate produced men of fierce and stubborn disposition. Buckle declared that the interruption of work caused by instability of climate leads to instability of character. Quatelet says that the number of crimes against property relatively to the number of crimes against the person increases considerably as we advance toward the north. Another eminent student of French criminal statistics, M. Tarde, confirms the opinion of the latter authority, and admits that high temperature does exercise an indirect influence on the criminal passions. But the most exhaustive investigations in this problem have been recently undertaken in Italy by Signor Ferri, whose criminal statistics of France show that crimes against the person rise with the temperature, those against property do the reverse. Clearly, climate has a great influence, but how about India, which is far less homicidal than any European country? India has not half as many homicides annually as England. With this example before us, then, whatever climate has to do with fostering these crimes may be obviated by a better form of social organization. Here racial distinction comes in, and Professor Ferri's table gives this sequence of races, namely: First, the Teutons; the Franco Celt; the mixture of Slav, Latin, and Teuton in Austria; then the Magyar; lastly the Latin. Latin-American, accordingly, is more homicidal than the Anglo-Saxon North.

With us, as in France, the care and treatment of degraded classes are extremely defective. There is too much "hot-house cultivation of crime," and far too little distinction in the treatment of those who are criminals by character and tendency and those who fall into error and vice from special circumstances of temptation. It is quite absurd to repeat imprisonment, even to scores of times, or to punish with short sentences crimes that indicate deeply-rooted defects of character, which only prolonged training can mitigate or remove; that, moreover, manifest mental disorder concomitant with active disease of brain or other organs, recognized or implied; which being pathological, require individualized treatment, restraint, or sterilization; but, if not of this class, many of whom are capable, under direction and authority, of productive labor, as distinguished from hospitals for the insane.

Great protection would result in our country, were the religious and civil authorities to take counsel from the medical profession, by excluding diseased immigrants on arrival at our ports; to object to the marriage and multiplication of those found defective in mind and body. This would not be opposed to the moral interests of the community, but rather in the line of physiological necessity. Evolutionary legislation would prevent early marriage, and forbid marriage where there is no means of supporting offspring. Human selection must be based upon natural selection in order to secure the best political and social evolution.

Offenders used to go free and multiplied their species; but when punishment became a certainty and criminals were isolated for years or transported, their race diminished. Were capital punishment abolished, the three-fourths of English murderers, for instance, that escape through aversion of juries and merciful people to inflict

a savage penalty, would be isolated for life, would be kindly treated, but must have no offspring. Instead of aiming at the murderer, evolution aims at the murder. A recent English writer on crime has said, that the uncertainty of punishment is the great bulwark of crime, and crime has a marvellous knack of diminishing in proportion as this uncertainty decreases.

The educated mind needs little to be convinced that the cause of crime and inebriety is often social and psychical, and, therefore, quite suggestive of a psychical remedy, which, as a matter of treatment, is of great import to society. Prevention, destruction, reformation are the requisites in dealing with crime, but the first is the most practical and valuable. Science and intellectual honesty must be brought to the aid of sentiment, before alienists, philanthropists, and governments can possibly reach the best results.

TWO CERVICAL MUSCLE ANOMALIES IN THE NEGRO.

By MIDDLETON MICHEL, M.D.,

Professor, Medical College of State of South Carolina, Charleston, S. C.

The labors of the dissecting-hall frequently reveal aberrations of structure that excite curiosity and baffle interpretation, if even the attempt be made to explain them. The student of human anatomy from his standpoint—the classic descriptions of his text-books—looks upon an accessory bundle of muscular fibres, an abnormal attachment, or a duplicative subdivision of the same, as little else than a caprice of evolution or an arrest or excess of development; for he has not yet learned the organo-genetic law which teaches that successional stages of embryonal development in the highest organisms constitute permanent conditions of structure in lower animals, or, as Haeckel frames it, "ontogeny is a short repetition of phylogeny."

Restricted in his study to man's anatomy without knowledge of comparative anatomy, he is unable to appreciate this fundamental law of biology, and is apt to consider abnormalities as trivial which are sometimes of great import. Specialization of function is so necessarily dependent upon differentiation of structure, that we ought not to be surprised to discover variations in the arrangements of parts that can be understood only by a reference to comparative anatomy. There is, indeed, scarcely any deviation of the muscular system but what is found to be a permanent, or at least a more frequent, arrangement in some lower animal; a circumstance that should guard us from considering incautiously such irregularities as important racial distinctions, unless their too frequent repetition points undeniably to a permanent reversion of development. The archetypal plan and homologies of the muscular system can be read correctly only after a comprehensive survey of the ontogenetic law of their development. The natural trend of simple analytic conjecture will often drift us into interpretations that regard as perfectly anomalous and beyond explanation what may be easily accounted for as a natural reversion toward some antecedent type of structure.

To accident or chance are necessarily relegated all disturbances in the accustomed uniformity of a recognized order of things, until some dominant principle or governing law be discerned to which such isolated facts become plainly obedient. It is then that the mind perceives the correlation that exists, and how the very irregularity itself serves frequently to emphasize the *law*.

As many still believe, the most salient exponent of mere coincidence is the phenomenon of teratogeny; yet on the alignment and direction of the biogenetic *law* of development we become divorced, even here, from the doctrine of chances, finding every aberrant step of evolution subservient to the controlling influence of the *law*.

It may perhaps be predicted that, as our science progresses, all unexplained coincidences or abnormalities of organic structure shall be eliminated from the domain of accident, and that there then shall be no such word as *chance*.

It has occurred to the writer that some simpler rules may also often guide the student of myology in his attempt to thread together the complexities involved in such anomalies as he may encounter. He would therefore remark, that every muscle has a determinate purpose to fulfil, indicated by its implantation upon the lever or part it is designed to move. Should this point of implantation not be reached, but the insertion occur at a wholly different point, then the muscle under examination ceases to be the one for which it appears to be a substitute. For example, the scalenæ are elevators of the ribs, and should of necessity preserve their costal attachments; now, should a muscular fasciculus be found inserted upon the clavicle, though emanating from the usual transverse cervical processes, we should in nowise regard the muscle as a representative of a scalenus, since, abandoning the ribs, it fails to fulfil its characteristic office. Should, however, the cervical insertion vary to any degree, reaching as high as the axis, the atlas, or even the occiput, provided the costal insertions be maintained, we are still dealing with the scalenus—the elevator of the ribs—though in this instance presenting an anomalous origin. Again, we would formulate another rule of guidance: that a muscle to claim its individuality, so to speak, must be indicated by at least one of its known and necessary attachments, and also by its nerve-supply. The absence of both attachments of a muscle at its accustomed points, would be a forfeiture of all claim to be regarded as any part of the muscle in question, as there could be no possible co-operation in the aims and purposes of such an aberration of structure.

The full significance of the above suggestions will be clearly brought out in the following interpretation here offered concerning a somewhat perplexing anomaly of muscles in the cervical region of a negro subject, that occurred in the dissecting-room this season (December, 1891) which we were requested to inspect and explain.

We were certainly in the presence of a rare occurrence of double cervical muscular anomalies on the same side of the neck, in the same immediate vicinity, and in such singular fellowship apparently as to impose the belief that they were related as duplications of one and the same muscle. It was the ready application of the above suggested rules that signally exemplified their importance in at once unravelling the difficulty.

The anomalous disposition was as follows: A muscle, about two-thirds of an inch in width, composed of parallel fibres with no intermediate tendon nor digastric structure, extended across the neck upward and inward, from the under surface of the clavicle near its acromial end to an insertion upon the body of the os hyoides; while immediately beneath this another muscle of equal size, attached to the clavicle at about the same acromial point, and running in parallelism with the former muscle, from which it was entirely independent, expanded into fleshy and short tendinous strips which were attached to the anterior tubercles of the third and fourth cervical transverse processes.

These superposed muscles, affiliated closely in size, direction, and in an almost common clavicular origin, were regarded naturally as a duplication of the same muscle; but whether one or both represented the omo-hyoideus, which was entirely absent on this side of the neck, seemed still doubtful in the minds of some.

Our explanation of the anomaly was, however, wholly different. This was no duplication of the same muscle, but two entirely distinct muscles. The hyoid connection of one of these muscles in a confluent tendon with the sterno-hyoideus at the same point, declared this to be the real omo-hyoideus attached at its proper upper insertion to the hyoid bones confluently with the sterno-hyoid muscles, though presenting the anomalous origin from the

clavicle, this being nothing more than a displacement of its more usual scapular attachment at the side of and over the coracoid notch of that bone to a near point upon the clavicle.

The underlying second muscle, connected neither with the scapula nor with the os hyoides, was evidently no representative of another double omohyoid; but, on the contrary, was a reproduction in the human subject of a well-known muscle in animals called the levator claviculæ.

Now, to justify this interpretation, we must first enter upon a full exposition of the morphology of the omohyoideus in the early stages of its development in the embryo, for this mode of inquiry can alone explain the cardinal point in its history, but little known, perhaps, even to the best informed anatomists, that this muscle was primordially one and the same structure with the sterno-hyoideus, and should still be regarded as the extreme external border of this last mentioned muscle. Indeed, at an early period of development there exists a broad sheet of parallel muscular fibres attached to the entire inferior or posterior surface of the clavicle, extending the length of this bone and even sometimes beyond it to the scapular notch; from this extensive attachment, muscular fibres, delicate and thin, converge to an apex-like insertion upon the body of the hyoid bone, presenting a fan-shaped muscle that occupies and covers in the inferior supra-clavicular triangle, and represents a permanent condition in some animals. This broad muscle degenerates, or is transformed later on, throughout the greater portion of its middle expanse into an aponeurosis, that becomes the middle cervical fascia, leaving as vestiges of its primitive muscular nature only the extreme internal and external marginal layers of muscular fibres attached still to the sternal end of clavicle on the one hand and to the coracoid notch of scapula on the other, so as to constitute the sterno-cleido hyoideus and omo-hyoideus, respectively. This shows the origin primordially of these two muscles, and the ready explanation without wonderment of any radiating muscular tissue, at any point from clavicle to hyoid bone, that we might ever meet with; this also accounts for the trace of an aponeurotic band often seen extending through the sterno hyoideus, and the more constant tendinous or digastric construction of the omohyoid, bound down toward the clavicle through the middle cervical fascia.

That such a transformation really takes place has been shown by those who have actually traced, under the microscope, muscular tissue running through the cervical fascia in stray fibres, convergingly toward the tendon of the omo hyoideus.

Thus through sufferance the omo-hyoideus is nearly always, but by no means invariably, attached to the coracoid border of the scapula, but occasionally to any point upon the clavicle, though most frequently toward the acromial end. This displacement of the omo hyoideus is familiar to all anatomists, for it has been the subject of very many memoirs by different authors.

The first of these muscles, then, in the anomaly before us, was evidently the omo hyoideus with a displacement of its scapular origin as above explained.

With regard to the other muscle, situated in a plane beneath, and extending from the cervical diapophyses to the clavicle, this so exactly corresponded to a muscle found in animals, that it was recognized to be the levator claviculæ known to comparative anatomists. This muscle exists in all the anthropoid apes, and has sometimes been discovered in man.

In 1869, Wood, at King's College, and in 1879, Testut, in Bordeaux, described it, the latter as follows: "J'ai observé entre le sterno cléido mastoïdienet le trapèze un muscle surnuméraire qui se rattache manifestement au levator claviculæ. Il naissait de la clavicule, dans une étendue de trois centimètres, par des fibres aponévrotiques excessivement courtes. Ses insertions antérieures étaient séparées du muscle cléido mastoïdien par un intervalle d'un centimètre; un intervalle double le séparait du trapèze.

"De leur origine claviculaire, les faisceaux charnus se portaient en haut et un peu en arrière, croisant le muscle omo-hyoidien, et se dissimulaient entièrement sous la face profonde du sterno-cléido-mastoïdien. En soulevant ce dernier muscle, j'ai vu mon muscle surnuméraire continuer son trajet vers la colonne vertébrale, diminuer peu à peu de largeur, et finalement se jeter sur un tendon légèrement aplati, qui venait se fixer au tubercule antérieur de l'apophyse transverse de la 3e vertèbre cervicale. J'ai observé ce muscle sur le côté gauche; le côté droit n'en présentait ancune trace."

This citation is here purposely given in the original French, since it accurately describes the muscle found in this negro subject on the left side only.

This is the first and only time I have met with it in man, but Wood has seen it five times, and Cuvier discovered it once, and this was in a negro.

This occurrence in a negro of the musculature of the anthropoid apes, if frequently repeated in the human subject, would point to an unmistakable reversion to an antecedent type of structure, and, as we have above stated, might be taken not only as a racial distinction separating the negro from the Caucasian, but would also indicate a lower grade of development in the black race. The levator claviculæ, however, has not often been found in the human subject, and so far more frequently in the white race than in the negro. There have been, since 1813 up to date, but 22 cases, including the one herein described, recorded of the presence of the levator claviculæ in man, and twice only has it been mentioned in the negro, so far as we can ascertain, once by Cuvier, and now by the writer.

These brief remarks illustrate the importance that should be attached to philosophical anatomy, which views man's organization as a higher and more specialized development of an underlying general plan of structure that pervades the entire class of vertebrates to which he belongs; the perfect knowledge of whose organization is obtained only through a rigid comparison of each member composing this special group of skeleton animals. Thus through transcendental anatomy, released from the mere accumulation of unmeaning facts that only burden the memory, we are enabled to interpret the anomalies and homologies of man's complex structure.

A Specific for Tetanus Discovered.—Dr. R. Schwartz, of Padua, announces the successful treatment of tetanus by means of injections of the tetanus antitoxin of Tizzoni and Caltani These experimenters succeeded in producing immunity against tetanus even in animals susceptible in a high degree, and have shown that the blood-serum exerts an antitoxic action, and is capable of producing immunity against and cure of the disease. They succeeded in obtaining this tetanus antitoxin in a solid state by the addition of alcohol to the serum, and by drying the precipitate *in vacuo*. As the disease in man is of longer duration and less certainly fatal than in many animals, there seemed to be good reason to hope that the tetanus antitoxin might be of great value. Gaglardi, of Molinella, treated a severe case by hypodermic injection of one gramme. All symptoms of tetanus disappeared and complete recovery ensued Schwartz relates at length the case of a peasant boy, aged fifteen, treated by him.

Chorea.—Out of a total of 18,074 children treated in five years at the polyclinic of the Charité in Berlin, Meyer found 121 instances of chorea, or a proportion of 6.6 per cent.; 11 of these cases (nine per cent.) were at the same time rheumatic; 3 had, along with their rheumatism and chorea, an organic affection of the heart; while 13 (ten per cent.) had chorea and heart disease without the rheumatism.—*Berliner klin. Wochens.*

CURIOUS FORMATION IN THE VITREOUS HUMOR.

By JOHN HERBERT CLAIBORNE, Jr., M.D.,

CLARKE COUNTY, VA.

Katie C——, aged eighteen, presented herself at the Vanderbilt Clinic on account of specks in her left eye. Eighteen months before, after a morning's work at weaving in black goods, she noticed, while at her mid day meal, a black speck on the sleeve of a friend who was sitting with her. See tried to pick it off, but, to her surprise, found nothing there. This frightened her friend, who thought she had lost her wits. Six months later another and smaller spot appeared. The large spot appeared to the right, the smaller to the left. Both moved with the eye, and each preserved its relative distance from the other.

The girl is anæmic and not over-robust. She says, however, her general health is good. Her parents are alive and healthy. Her mother has had eight children, two of whom died in infancy. The rest are alive and well. The vision in the eye affected is $\frac{20}{200}$; no improvement with glasses. The disk is white at the outer side. The blood-vessels are normal.

As shown by the cut, there is a patch of pigmentation at the macula. Around the edges of the patch there is slight evidence of atrophy of choroid. Farther out there is a very small pigmented spot, evidently of the same nature as the larger.

The most interesting appearance is the incomplete fillet in the vitreous humor that seems to embrace the disk and pass even beyond the region of the macula, stopping short of the second and smaller spot.

Just above the outer edge of the disk is a small, round opacity, from which a slender prolongation arises. Both the fillet and the globule change their relative positions with reference to the disk when the eye is rolled about. The disk was seen clearly with + 2.5 D. The fillet on the inner curve was seen most distinctly with + 5 D. and the small globule and prolongation with + 4 D. The fillet had the appearance of changing its place as it crept toward the macula.

The first explanation that suggests itself for the fillet and globule is, of course, that these appearances are remnants of the hyaloid artery. Yet this is far from satisfactory, as will be seen from a moment's reflection. The fillet had a grayish pellucid look that suggested connective tissue, and the globule suggested the appearance of an air-bubble by the brightness of its edge. It seems reasonable to suppose that both were due to the same cause. After the condition of her eye was explained to the patient she said she could see the fillet.

The interest and value of this report is vastly enhanced by the excellent drawing, for which I am indebted to Dr. Ward A. Holden.

Progress of Medical Science.

Borate of Soda in Epilepsy.—Dr. Mairet finds that, compared with the bromide of potassium, the borate of soda is of real value in the treatment of epilepsy. The attacks decrease under its use, and may be suppressed even for many months at a time. It acts better than the bromide of potash in symptomatic epilepsy. The bromide, on the contrary, gives better results than the borate of soda in nervous epilepsies, and in cases of this order it is only when the bromide has failed that borax should be tried.—*Le Progrès Médical.*

Microbes of the Dead Sea.—For a long time there was doubt as to whether any organism, animal or vegetable, lived in the Dead Sea. Now the question is solved by a patient Frenchman, Dr. Lortet, who finds at last, in water from the Dead Sea, specific microbes of gangrene and tetanus. Inoculated rabbits promptly expire, which proves that the classic Lacus Asphalites is more alive than was formerly supposed.

Treatment of Ringworm.—Dr. Goldsmith writes to the *British Medical Journal* that, when all other remedies had failed to effect a cure in three cases of ringworm of the scalp, in his own family, he tried Dr. Illingworth's method with prompt success. The formula for this strong blistering fluid, one application of which its origi nator claims will cure an ordinary case, is as follows :

℞. Hydrarg. biniodid..... ℥ ss.
Sal. sodii iodidi (1 in 4)..... ℥ ss.

A small portion of this is to be diluted with three parts of water, at the time of application. It is to be painted on with a camel's-hair pencil.

Hydrastis Canadensis is said to exert a very marked effect upon night-sweats, at the same time that it has a controlling influence over pulmonary hemorrhage, in phthisis. Thirty drops of the fluid extract are recommended by Cruse to be given at evening.

Septic Infection from the Umbilicus.—Dr. Eröas (*Wiener Med. Wochens.*, No. 41) says that septic infection associated with the detachment of the cord is a frequent source of fever in the new-born, and has a marked effect on infant mortality. He has studied the question in connection with one thousand births at the Buda-Pesth Obstetric Clinic, finding fever present in 450 instances, 220 of which were associated with some pathological condition at the navel. Death occurred in 8 cases. Gangrene of the cord was found in 81 instances; sloughing and protruding stump, each 55; emphalitis, 24, etc. Thorough antisepsis is recommended.

Methylene Blue in Neuralgia and Malaria.—According to the *Berliner klin. Wochens.*, No. 39, Drs. Guttman and Ehrlich have found a decided effect from methylene blue in malaria. Ten centigrammes of the chemically pure drug are given in capsule five times daily. Dr. Immerwahr states, in the *Deutsche Med. Wochens.*, October 8, 1891, that under certain circumstances this same drug, given three times daily in dose of from two to five grains, gives relief in neuralgia, muscular rheumatism, and the nerve pain of herpes zoster, but not in sciatica. Further trial in both neuralgias and malarious fevers must be made before the true value of the drug is known.

MEDICAL RECORD:

New York, January 30, 1892.

MYOPIA AMONG SCHOOL-CHILDREN.

THE hygiene of the eye is of particular interest to everyone, especially to parents and the guardians of children. However badly spoiled adults may be physically, there is seldom a soul so dead as not to rejoice in the perfections of childhood, and whatever will secure for it immunity from future disaster. Some interesting facts concerning the modern eye and its care were elicited in a recent meeting of the French Ophthalmological Society. Abstracts of the discussion are to be found in *Mercredi médical*, December 9, 1891. According to Dr. Motais, who has examined five thousand school-children of different grades, and the families of three hundred young myopic patients, myopia is not a disease from the point of view of onset and origin. It is a normal development, an adaptation of the eye to new functions—in other words, to near vision. It is the outcome of city life and civilization. The human eye is hypermetropic to the degree of a half or one diopter. Emmetropia, which is given as the rule, is the first result of adapting the eye to the needs of civilized life. The emmetropic eye is a candidate for myopia, which appears between the ages of eleven and thirteen, and is gradually progressive. Myopia is hereditary in sixty-five per cent. of all cases. In eighty out of every hundred myopic persons, the condition of the eye is transmitted from the father to the daughter, and from the mother to the son, or from grandparents to grandchildren. Hereditary myopia is more sharply defined than the acquired form, it reaches a higher degree more rapidly, and complications more often accompany it. Acquired myopia has a tendency to become hereditary. As education is becoming more and more general, even among girls, Dr. Motais fears for the future, evidently forgetting the tendency of human nature to revert to original or primitive types. As prophylactic measures, good light and hours of study that are not too long are important, together with the overcoming of the tendency to spasm that often precedes the development of myopia. As near sightedness progresses there is sometimes depression of the posterior pole of the eye, and sometimes destruction of the anterior segment. Extraction of the transparent crystalline lens is justly considered dangerous, though surgical interference is advocated by Dr. Galezowski when there is exaggerated curve of the cornea. In twelve instances he has removed a semi-elliptical portion of the cornea near the centre, following the method adopted by him for staphyloma. In every case the operation has been followed, without accident, by diminution of the myopia from two to five diopters.

The influence of race on near sightedness presents some points of interest. The children of German emigrants present a slighter degree of myopia than the children of other races in America, far less than German children of the same age born in Germany. In foggy regions there is more myopia than where the atmosphere is clear. The hygiene of the eye, according to Dr. Nimier, is indispensable, yet too much is not to be expected from preventive measures. The etiology of myopia is complex. Near work, heredity, growth, are all factors. Yet this condition is sometimes due to congenital malformation of the eye. At the hospital of Val-de-Grâce there is a record of forty-nine cases of aniso-metropic myopia, sufficient to establish the existence of this abnormity.

HYSTERIA IN THE NURSERY.

THE Paris correspondent of *The Lancet*, December 12, 1891, states that Dr. Chaumier, of Tours, recently read a paper before the Académie de Médecine on "Hysteria in Infants." Notes of two hundred cases, observed in children under two years of age, led the worthy Frenchman to believe that what ignorant mothers, nurses, and doctors have considered convulsions, "tantrums," or fits of bad temper, are in reality more or less severe attacks of hysteria. According to Dr. Chaumier, the symptoms of the mildest attack of infantile hysteria are repeated, and causeless accesses of rage manifested by loud cries. More serious attacks may be recognized by a stiffening of the limbs, with turgidity of the face, and possibly tremblings. Some hysterical babies will roll on the floor, or the bed, executing extensive movements of the arms or legs, without losing consciousness. Others lose consciousness, and the body is either rigid or limp. There are also *grandes attaques* even among babies. The prognosis is good, and what may be denominated "cradle hysteria" is more amenable to treatment than the drawing-room variety.

REST AND TRAVEL AS THERAPEUTIC AGENTS.

THERE are some good points made in *The Lancet*, December 12, 1891, in regard to the medical uses of rest and travel. Many of the toil-worn and worried need only to lie fallow for a time, and give tired nature a chance of recuperation and repair. To obtain conditions for rest of the right kind is often difficult, for there must be change and variety, and yet travelling is not always restful. Perhaps the ideal rest is a sea-voyage, far from the madding crowd, with its pure and invigorating atmosphere, its constant passive motion without fatigue, its change of scene and novel conditions of life, its freedom from care, worry, and excitement. There is, of course, the possibility of sea-sickness and bad weather, the separation from home and friends, and some slight risks. But these are not insurmountable obstacles. The rest and health seeker must avoid one snare, and that is imprudence on landing. To resume prematurely habits of activity after the luxurious rest of a sea-voyage is the height of folly. Rest on land must follow that upon the water,

and all efforts be gradually and systematically resumed. For an ideal combination of rest and travel, *The Lancet* suggests the voyage from Cairo to the Nile cataracts, in a Nile steamer. The climate is perfect, and the region abounds in interest. The season is from November to March, and continuous sunshine may be counted upon as soon as Luxor is reached. The nights are sometimes very cold, which is the only drawback to this adorable climate. Travel and rest may also be combined on the Algerian verge of the Sahara. Various oases—as Biskra, perhaps the best known—are accessible by rail from the seaports of Algeria, regions of sunshine, absolute calm, and remoteness from the stress and strife of civilization. And there are mountains in Africa that are a perfect delight to the weary of brain and tired of heart. The choice of locality depends upon the balance of symptoms and the insight of the physician.

GRIP AND THE COUNTY SOCIETY.

Before the Medical Society of the County of New York epidemic influenza was again recently considered. Its diagnostic features were discussed by Dr. E. G. Janeway, who thought it somewhat difficult to distinguish absolutely the identity of isolated cases. In the presence of the epidemic, there was a too ready tendency to class ordinary indispositions under the head of epidemic influenza. Follicular tonsillitis, ordinary lobar pneumonia, and meningitis were sometimes mistaken for grip, and the early symptoms of small-pox might trip up the unwary in diagnosis. To the belief that grip has certain marked characteristics which clearly distinguish it from all other diseases, Dr. R. W. Wilcox inclined, the first of these characteristics being the suddenness of the attack; the second, the multiplicity of the symptoms; the third, the variability of the symptoms; the fourth, an amount of depression out of all proportion to the physical disturbance; and the fifth, more tardy convalescence than in other diseases of the same severity.

Instead of complications of grip, Dr. W. H. Draper preferred the term complexities of grip. The disease being a general constitutional disorder, due to essential infection, expresses itself in a variety of forms traceable to a specific poison. Paresis and paralysis of ocular muscles, Dr. Pooley noted as some of the eye-troubles really due to epidemic influenza. Its aural manifestations, Dr. O. D. Pomeroy thought, presented nothing of marked characteristic interest beyond their intensity and a tendency to cell-proliferation. The nervous phenomena were considered by Dr. L. C. Gray, who included among them prostration—severe out of all proportion to the fever—spurious melancholia, sometimes mania, nona, and hallucinatory insanity. Dr. H. D. Chapin found grip less common and less severe among children than among adults, though the presence of the epidemic rendered existing respiratory troubles more serious. Measles was often mistaken for grip in children, though the latter disease was ushered in by vomiting, lasting several hours or a day, and only occasionally were eruptions among its manifestations.

The treatment of epidemic influenza was the division of the subject assigned to Dr. F. Delafield. There being no specific, any more than in other infectious diseases, rest in bed, good nursing, the relief of pain and distress, were naturally the chief factors in treatment, the frequent complications receiving attention as they presented themselves. For headaches and neuralgia, phenacetin in small and frequent doses gave the best results. To improve and sustain the circulation, digitalis, aconitine, veratrum viride, and strychnine, were well-known drugs that in combination were admirably suited to the arterio-cardiac exigencies of grip. Alcohol might also be needed. Pains in the throat were best relieved by aconite and salycilate of soda. Dr. Beverley Robinson spoke of the efficacy of local applications to the throat, even when local manifestations were not present, as tending to relieve peripheral irritation.

The rest of the discussion was postponed till the next meeting, on account of the lateness of the hour. That epidemic influenza continues to be a live subject is rather a good thing, for under the circumstances it is hardly possible for it to escape detection a second time, and the history of its reception here, three winters ago, has no excuse now for repeating itself.

A NEW THEORY OF INTERMITTENT FEVER.

The influence of fashion in medical theory and practice is so strong that most men, even while doubting the truth of a prevailing idea, hesitate to raise their voice against it, fearing either ridicule or contemptuous silence. It is, therefore, consequently refreshing to meet with an occasional courageous spirit who not only has views of his own that run counter to the dominant theories, but dares to express them in the face of the almost unanimous opposition of the medical world.

Dr. Matthew D. O'Connell, of the Indian Medical Staff, is one of these hardy souls, who has a theory about ague which he does not hesitate to express. Writing in the *Indian Medical Gazette* for November, 1891, he says that, while not disposed to question the influence of the presence in the blood of a micro-organism, animal or vegetable, in the production of remittent fever or pernicious malarial fevers, he thinks that another hypothesis is not only possible, but is fully adequate to explain the facts of ague and its consequences.

This hypothesis is that ague, or intermittent fever, is due to an intermittent excess of water in the blood, and that this intermittent excess of water in the blood, or hydræmia, is the obvious result of exposure to the meteorological surroundings (heat and moisture) which go to make up what we call a malarial climate.

The facts which have led him to the belief that intermittent fever is due to an intermittent hydræmia are as follows: 1. There is known to be excess of water in the blood in all fevers. 2. Excess of water in the blood, or hydræmia, will cause fever. 3. The meteorological conditions (heat and moisture) which make up what we call a malarial climate, are such as must, by preventing its excretion, produce an intermittent excess of water in the blood, or hydræmia. 4. Free elimination of water from the blood of a person suffering from ague reduces the temperature to normal. 5. Excess of water in the blood, especially if intermittent, will produce all the usual sequelæ of ague, viz., (*a*) enlargement of spleen, (*b*) leucocythæmia, (*c*) pigmental deposit in organs. 6. All successful treat

ment of ague reduces the quantity of water in the blood. 7. Change of climate cures the disease.

We cannot say that all these alleged facts are actual facts, or, admitting them, that they prove Dr. O'Connell's theory. Still, as we said above, it is refreshing to find one who is bold enough to attack existing and generally accepted theories, and we believe such a man deserves to have his views made known.

THE COMMUNION AND PROHIBITION.

The pastor of a church in a Connecticut town announces that hereafter he will use no wine in the Communion Service, but will present the worshippers with a cup containing colored water only He is an ardent Prohibitionist, and fears that some devout communicant may be led from the path of rectitude through a passion for drink, reawakened while partaking of the Sacrament. While it is not exactly within the province of a medical journal to discuss purely theological questions, yet we cannot but wonder at the apparent lack of faith in a Christian minister, who can believe that anybody could be plunged into sin by doing what his religion commands him to do; for it is evidently the duty of a professing Christian to obey the precepts of his Church.

But there is a medical side to the rite of Communion concerning which a word may be said. And that is the passing of the cup to a whole line of communicants for them to drink from, one after the other. There are certain diseases which are highly infectious, and which might readily be conveyed to the well by means of a cup moistened with the lips of others. We do not refer to syphilis only, although the danger of that must be apparent to all, for it is not every earnest Christian who has always been a Christian, or who has not at some time strayed from the narrow path; but there are other diseases the contagium of which may be spread in the same manner. In the Catholic Church this danger does not exist, and while desiring in no way to enter theological fields, we believe that the Protestant Churches might do well to consider, in these days of hygienic enlightenment, whether they acted wisely in departing from the ancient Catholic custom of giving the communion in one kind only. If colored water may be substituted for wine, on teetotal grounds, why cannot the use of liquid of any kind be abandoned for hygienic reasons? The Connecticut pastor has by his innovation escaped but one of the dangers, and that one the lesser of the two.

THE AMBULANCE SURGEON.

The other day a sailor from one of the vessels in the harbor went off on shore leave, and of course got drunk. On his return to the ship he fell down a hatchway and was picked up insensible. An ambulance was sent for, but the surgeon said it was only a case of alcoholism, and would not take it. The man was left in the police station, and as he did not improve the ambulance was sent for again, and then a third time; but the surgeon, with his wide experience, continued to diagnose the case as a simple "drunk," and would have nothing to do with it. Finally another ambulance was called and the man was taken to another hospital, where he promptly died from a fracture of the skull.

This is not the first time that an ambulance surgeon has made it evident that he has yet something to learn. We know these gentlemen are fresh from college and have all the wisdom and infallibility of youth, yet they should remember that modesty is a virtue that becomes even the wisest of men, and that, incomprehensible as it may seem to them, all creatures, even uniformed ambulance surgeons, for whose chariot the proudest truck-driver must make room, are prone to err.

The ambulance system exists for the purpose of extending relief to the sick and the injured, and the ambulance surgeon who refuses such aid is unfit for the responsible position he fills—or rather, occupies. There are, of course, cases where it is difficult, if not impossible, to diagnose the condition off-hand, but it is far better to take an occasional "drunk" to the hospital than to leave a man who is seriously injured uncared for in the police station. When the fact that the case is something more than alcoholism is apparent even to the police, who are not celebrated for their diagnostic skill, it is inexcusable in a surgeon to neglect it. Bumptiousness is not one of the qualifications that commend a public servant to public favor, and it is decidedly out of place in a hospital interne or ambulance doctor.

News of the Week.

The Influenza Bacillus.—As we go to press we receive from Dr. R. Pfeiffer, of Berlin, a preliminary report of his discovery of the influenza bacillus. He says: "In every case of influenza the bacillus is found. Control experiments demonstrate that the bacillus is absent in ordinary bronchial catarrh, pneumonia, and phthisis. The bacillus disappears with the disappearance of the disease. The bacillus itself is a very small rod about the thickness of the mouse septicæmia bacillus, and but half its length. Very often three or four are found arranged in chains. With basic aniline color they are difficult to stain, but are easily stained with diluted Ziehl's solution or with hot Löeffler's methylene blue. I have succeeded in growing two generations of the bacillus on dextrose-agar (one and one half per cent.). The animals inoculated were rabbits, guinea-pigs, rats, mice, pigeons, and monkeys. The latter and rabbits only gave positive results. The infection is probably caused from the bacilli in the secretions of the naso-bronchial tract, and the prophylactic method would be to destroy the bacillus by neutralizing these secretions. Dr. Kitasato has been able to generate the fifth generation on glycerine-agar."

This is the first authoritative statement made in regard to Pfeiffer's discovery.

To Prevent Tuberculosis.—A rigid quarantine has been established by New Hampshire to prevent a spread of tuberculosis from Massachusetts. Last year, according to a report just issued, one hundred and eleven subjects of tuberculous disease in New Hampshire were condemned and killed. Investigation has shown that the disease was brought in from Massachusetts, and notice has been given that all cattle coming from that State must in future submit to quarantine regulations. The subject of tubercle referred to as having been put to death were cows.

Self-help.—The *Doctor's Weekly* is honest enough to have a column headed "Cribbings." It has another called "Among Our Exchanges," and under the latter, in last week's issue, it places an abstract of Boeckel's article on treatment of abscess of the breast, taken bodily from the RECORD of January 2d and credited to the *Gazette Médicale de Strasbourg*. At the head of the editorial column of the *Weekly* stands the question "Will you aid us?" We should be pleased to do anything in our power. We always like to help the man who helps himself, but when an editor helps himself to our literary efforts, and has a "cribbing" department, he should use it.

A Strange Accident.—A correspondent of *The Lancet* writes in a recent issue that, as he was about to examine a patient's chest with a binaural stethoscope, one of the ivory ear-pieces fell off unobserved by him. He let the instrument go in the ear in the usual way, and, the spring being somewhat strong, the uncovered end pierced the membrana tympani.

Sir William Thomson has been made a peer by the Queen.

Mr. Berkeley Hill, Vice-President of the Royal College of Surgeons, has recently died in London.

Typhoid Fever is very prevalent in Athens. A railway tunnel is being constructed in the lower part of the city, and it has been necessary to interfere more or less with the main sewers. The epidemic is attributed to this cause.

A New Remedy for Rheumatism.—At a recent meeting of the Berlin Medical Society Dr. Paul Guttman, of the Moabit Hospital, recommended a new medicament called Salophen. It is a finely crystalline substance, easily soluble in ether and in alcohol, but not soluble in water. It consists of salicylic acid and acetyl-paramidophenol in almost equal parts. Six to eight grammes can be given daily without injury to the patient. In acute articular rheumatism it soon removes the pain and the swelling. Sometimes, however, it fails to produce these effects, and it does not protect against relapses. In chronic articular rheumatism also it may be tried with success. It has a slight antifebrile effect.—*The Lancet.*

M. Villemin was, at the last election of the Paris Academy of Medicine, chosen Vice-President of that body by an almost unanimous vote. According to the custom of the Academy, the Vice-President of one year is advanced to the Presidency the year following.

Cremation in France.—During the year 1890 there were over 150 persons cremated in Paris, as against about 50 the year before. The cost of the operation in France is very small, the total expenses only amounting altogether to 31 francs 60 centimes. Since October 1, 1891, in addition to the ordinary cremations, more than 4,614 bodies have been sent from the hospitals to be cremated.

Professor v. Bardeleben, of Berlin, celebrated his semi centennial of medical practice on December 15th. The Emperor conferred on him a patent of hereditary nobility in recognition of his services during the last illness of the Emperor Frederick.

Influenza at Berlin.—The epidemic of influenza in Berlin has been much severer in character this year than even those of the two preceding winters. The highest number of deaths per week, from this cause, registered in the winters of 1889–90 and 1890–91, was 30, while this winter the number has reached 80 per week.

Modified Tuberculin.—Several physicians in this city are conducting experiments with Koch's modified tuberculin. Thus far no results of an encouraging nature have been recorded. We would suggest the substitution of cod-liver oil as being more likely to benefit the patients.

Purifying Water by Electricity.—Experiments which have been made recently in Germany, to determine the value of electricity in purifying water, show that it has this effect in a measure. The amount of organic matter in the water was reduced, though not entirely removed.

An Opening for a Medical Man.—An esteemed contemporary announces with a sigh that there is not one man in Philadelphia who practises on rectal affections exclusively.

A National Medical Practice Law.—The *American Doctor* says that the present system of State examining boards is a nuisance, and thinks that there should be some national law to regulate the practice of medicine, so that a competent man may exercise his rights to practise in any State of the Union without being bothered by a little board in every State he may enter.

Heavy Damages in a Malpractice Suit.—Four thousand dollars was the amount to which the jury considered the patient damaged in a suit for malpractice recently brought against a well-known practitioner of Nashville. The suit, as we learn from the *Nashville Journal of Medicine and Surgery* for January, 1892, was based upon the following circumstances: A child had sustained a simple fracture of the humerus close to the elbow-joint, to which the doctor was called. The fracture was reduced and the limb put up in a plaster-of-Paris bandage. Considerable pain ensued, but the bandage was not removed until the following day, when another physician was called in to the case. On removal of the dressing, the entire arm and hand were found in a bad condition, presenting signs of impending mortification. Active treatment saved the limb, but extensive sloughing and subsequent cicatricial contraction led to considerable deformity and impairment of function; hence, the suit.

Light as an Anæsthetic.—A Russian physician says that the electric light relieves pain in many cases almost instantaneously. For the cure of neuralgia he throws a beam from a bright arc light on to the painful area by means of a powerful reflector, or uses direct illumination by means of a condenser. In this way, it is claimed, the most intense pain, provided it be superficially located, may often be relieved at once without the use of anodynes.

The Columbian World's Congress of Pharmacists.—A comprehensive series of World's Congresses will be held at Chicago during the season of the World's Columbian Exposition of 1893. These Congresses will be of a dual character, some of their sessions being devoted to popular addresses of general interest, and others to the discussion of living questions such as the specialists who compose the several respective congresses may present. There will be, among others, a Columbian World's Con-

gress of Pharmacists. The World's Congress Auxiliary, through its committee, also invites the International Pharmaceutical Congress, the American Pharmaceutical Association, all of the State Pharmaceutical Associations and Boards of Pharmacy, and the Colleges and Schools of Pharmacy, to meet in Chicago at about the same time. The Seventh International Pharmaceutical Congress will probably be called to meet at the same time and place. There will be no conflict whatever between it and the Columbian Pharmaceutical Congress. Preliminary correspondence between the American Pharmaceutical Association and the representatives of the Sixth International Pharmaceutical Congress has been going on for some time, and it is hoped that the Special Committee of the Association will be enabled at an early day to enter actively upon its duties to arrange the preliminaries in co operation with the World's Congress Auxiliary of the World's Columbian Exposition.

The Surgical Aspects of a London Fog.—During the week ending December 26th, which was characterized by a very heavy fog, the accident cases received at one of the London hospitals consisted of 51 fractures, 6 dislocations, 24 sprains, 4 concussions, 13 contusions, 50 lacerated scalp wounds, and 1 rupture of the globe of the eye. The minor casualties treated consisted of : Sprains or contusions of the shoulder, 23 ; of the elbow, 13 ; of the wrist, 23 ; of the fingers, 12 ; of the hip, 9 ; of the knee, 10 ; of the ankle, 24 ; of the toes, 6 ; of the back, 18 ; of the side, 23 ; of the jaw, 2 ; 8 lacerations of the finger, 4 of the face, 8 of the scalp, 5 of the forehead. In twenty-four hours—December 25th and 26th—11 cases were seen of fractured radius either with or without fracture of the ulna.

Tuberculin in London.—Between December 6, 1890, and April 5, 1891, twenty-eight cases of phthisis were treated by means of tuberculin at the Hospital for Consumption and Diseases of the Chest in London. In the report recently made by Drs. Williams and Tatham upon these experiments, it is stated that "the tuberculin did not favorably influence the course of the disease in the majority of cases; that in some the effects were detrimental; and that even in the stationary and improved cases it was difficult to ascribe any distinct improvement to the injections, which might not have been equally attained under the treatment ordinarily employed in the hospital." Two cases of lupus treated by tuberculin "showed marked temporary improvement, followed by a return toward, if not actually to, the condition preceding the commencement of the treatment, when the injections were stopped; and even before stopping the injections, the retrogression had already set in."

A Curious Coincidence.—Dr. E. Schech, of Munich, while performing recently a difficult and tedious operation on the larynx, was himself suddenly seized with spasm of the glottis. This was followed by tetanoid convulsions, and for a time it was feared that he could not recover, but fortunately these fears were not realized.

The Marine Hospital Service.—Dr. W. W. Wyman has been nominated by the President supervising surgeon-general, a position that he has filled for a number of months under a temporary appointment during the recess of Congress.

The Journal de Médecine de Bruxelles, the official organ of the Royal Society of Medical and Natural Sciences of Brussels, has completed its first half century of existence. It will appear henceforth as a weekly instead of a semi-monthly publication.

Dr. St. John's Dinner to the Bergen County (N. J.) Society.—Dr. David St. John, of Hackensack, N. J., the founder of the Hackensack Hospital, gave a dinner at the Hackensack House, Wednesday evening, January 27th, to the Consulting Staff of the Hospital, and to the Bergen County Medical Society. Seventy-five guests were present. Dr. Neer, President of the Bergen County Society, presided. Dr. J. Leonard Corning, of New York, was toast-master, Dr. H. C. Neer spoke on behalf of the Society, and Mr. Johnson for the Hospital. These were followed by general responses from the New York guests, Drs. David Webster, George F. Shrady, Reginald Sayre, R. Newman, W. Gill Wylie; and by Senator Winton, of New Jersey, Mr. Dickinson, of Jersey City, and the Rev. Mr. Johnson, of Hackensack.

Obituary.

SAMUEL H. CASE, M.D.,

ONEONTA, N. Y.

Samuel H. Case, M.D., died on Monday, the 18th inst., at the age of eighty-three years. He was born in Franklin, N. Y., December 14, 1808. His parents were among the earliest settlers of the town of Franklin, having settled there from Connecticut in 1792. The Case family came of sturdy English stock and emigrated to America about the year 1630, settling in the town of Colchester, Conn. The father of Dr. Case was one of a family of eight sons who settled in Franklin at the date above given, driving their cattle and sheep before them into the wilderness. Eight days were consumed in the march from the Hudson River.

Dr. Case's early education was begun in the primitive school of the neighborhood, and afterward continued at the old Delaware Academy at Delhi, N. Y. He began the study of medicine with his brother-in-law, the late Dr. Almiron Fitch, of Delhi, and subsequently completed his course at the medical college at Fairfield, Herkimer County, from which institution he was graduated February 3, 1829.

He was the second regular physician to begin his professional work in Oneonta, Dr. Joseph Lindsay, his senior in years, having settled here in 1807. The old doctor and the young doctor worked harmoniously together in the little hamlet and throughout the wide district that extended from one clearing to another for many miles.

No physician in the State was more faithful in his professional duties, more faithful to the public, than was Dr. Case. His ride extended over several towns of Otsego and Delaware Counties. There was no weather so inclement that he did not breast it, no ride was too long for him, and no patient was neglected because he was poor.

Dr. Case was married in 1834 to Emilia A. Meigs, a daughter of Edmund Meigs, a prosperous business man of the town. By this marriage he had two children. The doctor was many years town superintendent of schools, supervisor, railroad commissioner, pension examiner, and in whatever capacity he acted he was faithful to the trust reposed in him. The rare combination of qualities that made Dr. Case the model husband and father, the good physician, the patriotic and public-spirited citizen, will long be held in affectionate and grateful recollection.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 17, 1891.

D. B St John Roosa, M.D., Vice-President, in the Chair.

Streptococcus Osteomyelitis.—Dr. Henry Koplik presented the first paper on this subject. Later Dr. Van Arsdale read one on "The Surgical Considerations of Streptococcus Osteomyelitis," after which a general discussion took place.

Dr. Koplik's experiments had been carried out at the Carnegie Laboratory. In his opening remarks he showed that the terms septicæmia and pyæmia had been largely used interchangeably, and that only rather indefinite attempts had been made to analyze the different forms of infection according to the micro organism producing them; that at the Pasteur Institute alone had the influence of the streptococcus in the production of certain cases of osteomyelitis been pointed out. The special object of his paper was to show a form of osteomyelitis which was due to a different kind of micro organism from that which had engaged attention during the earlier studies of the subject. While formerly the staphylococcus was looked upon as generally the cause of osteomyelitis, later any pus-producing microbe was thought to be able to cause an acute attack of this affection. Having referred briefly to the experiments of Lanalongue in producing an osteomyelitis in animals by injections of the streptococcus, the author related the history of some cases which had come under his observation, and from which he was enabled to make cultures of the streptococcus and experiment on rabbits, etc. The streptococcus osteomyelitis under consideration sometimes followed one of the acute exanthematous diseases, diphtheria, inflammation of the umbilicus, etc., the germ gaining entrance to the circulation through an abrasion of the skin or mucous membrane in a patient already reduced in health. In one of his five or more cases the pain and swelling of the limb followed a suppurative condition at the umbilicus in a child some weeks old. The swelling and suppuration first affected the knee, then the hip, and then other joints, and the child died. The second case was one of streptococcus invasion following scarlet fever, which produced multiple joint inflammation, with suppuration and death from exhaustion. The next case occurred in a child, aged ten months, which had had fever and cough; later, when first seen, there was a bronchopneumonia, swelling of the wrist, and elbow-joints developed, which extended to other joints. From them yellowish pus was withdrawn. The fifth case was also one of multiple joint affections, which went on to exhaustion.

The experiments were carried out by withdrawing some of the pus. The streptococcus was found, cultures were made, and with the pure culture local inoculations were made, or the germs were injected into the general circulation. In the case of rabbits, death took place only after injections into the circulation. The affected joints following the experiments contained no other microbe than the streptococcus. The spleen was also enlarged, and the blood, spleen, and sometimes other organs, as well as the joints, showed pure streptococci. There was no necrosis of bone, no periosteal or subperiosteal swelling. The medulla of the bones making up the inflamed joints was invaded with streptococci; they were also seen in the Haversian canals.

He said these experiments were made before he had become acquainted with the work of the French school, and they led to the conviction that there was a form of acute osteomyelitis secondary to invasion of the system by an organism identical with the streptococcus pyogenes. All the cases belonged to the class which had been termed septo-pyæmic.

Dr. Koplik's views of the treatment were in harmony with those of Dr. Van Arsdale. The same cause did not always produce a type of disease of the same severity, the difference being due, at least in part, to the general systemic condition. He approved of an attempt to shut off the invaded bone from the rest of the skeleton with a view to remove or limit the infection. Diagrams of the streptococcus in pure culture, in matter withdrawn from a joint, and in the Haversian canals, were exhibited.

Dr. William W. Van Arsdale then presented his communication on the surgical features of streptococcus osteomyelitis. He would not have been encouraged to do this had not a case treated according to ideas based on the recent view of the etiology of the affection recovered. It was the third case in the list reported, and occurred in a girl, ten months of age, who when first seen had pneumonia, then there developed a fluctuating swelling of the wrist which extended up the forearm; the elbow-joint also became swollen. He incised and drained the wrist-joint, treated it antiseptically, and put on a splint. Two days later disorganization of the lower forearm seemed to have increased in extent and gave indication for further treatment, but owing to the presence of the pneumonia operative procedure was postponed for fourteen days; then there being evidence of pus in the elbow-joint he operated for that, found necrosis in the epiphysis; the bone proved necrotic in its entire extent and was removed *in toto*. The periosteal covering had been so changed as to be unrecognizable, due probably to the delay in the operation and extension of the inflammatory process. The condition of the patient being one of extreme prostration, a bad prognosis was given, yet she recovered, but disappeared from view, so that further management could not be carried out. He thought this was better than amputation, and less severe, and for that reason less dangerous.

The author put much stress on early recognition and interference. The experiments upon animals seemed to show the presence of inflammation in the medulla before the development of disease in the joints, and to wait for erosion of cartilage to take place in the joints was to make unnecessary delay. If the diaphysis were taken out at an earlier period possibly extension of the disease to the joint might be avoided and function retained. Unfortunately the physician often saw the case late, or parents hesitated to grant permission to interfere. If bone failed to reproduce and it became desirable or necessary to amputate the limb subsequently, it could then be done with less danger than it could have been done while the patient's condition was so low. The streptococci could not be reached by simply washing out the medullary canal, for, as shown in the diagrams, they penetrated the Haversian canals also. Where there was evident implication of the internal organs one might hesitate, in view of the much more unfavorable prognosis, to attack the affected bones. Nevertheless, the removal of every focus from which renewed invasion of the system by germs and their toxic secretion was taking place should give the patient a better chance. Happily the streptococcus showed special preference for bones and joints, so that invasion of the organs might recede with radical measures directed to the first named seat of infection. The author distinguished between the form of osteomyelitis under consideration and the simple catarrhal form of Volkmann, which was much milder.

It would be observed that in streptococcus osteomyelitis the disease was due to a special germ which reached the interior of the system, and which might not cause any symptoms at the point of entrance, but it showed a selection of bones and joints as a place for development, so that the joint affections were likely to be multiple. The author thought more radical surgical measures should be adopted than heretofore; that the interference should not relate alone to the joint, but also to the bones going to make up the joint. An incision should be made along the shaft of the bone, and as much as might seem neces-

sary should be subperiosteally removed. If subsequent reproduction of bone did not take place, precaution should be taken against shortening, and secondary amputation might, if desirable, be made. Nor should the fact that the epiphyseal cartilage had become disintegrated interfere with the extraction of the foci of osteomyelitis; the cartilage should be treated in conjunction with treatment of the joint. If it was possible to save the epiphyseal line it might permit of reproduction of bone and joint function. As to the best and safest antiseptic in children, he recommended creoline.

Dr. F. S. Dennis related an interesting case in which the staphylococcus albus had caused an osteomyelitis affecting the tibia in a lad whom he presented and who had been brought to Bellevue Hospital from the Chambers Street Hospital under the supposition, he believed, that the symptoms were due to typhoid fever. This was excluded by Dr. Janeway. The boy entered Dr. Dennis's ward, and while the symptoms were much like those of typhoid fever, there was one which led him to explore the tibia. Over this bone was excruciating pain, and on cutting down upon the bone nothing abnormal was found until it was trephined, when pus welled up from the interior. He gouged out the medullary canal, thoroughly cleansed it, and the boy had practically recovered. The pus contained only the staphylococcus pyogenes albus, whereas the rule was to find in osteomyelitis and joint affections the staphylococcus pyogenes aureus.

Dr. A. G. Gerster said he had been much instructed by the papers, that he was glad to learn of the distinctions between the several cases of osteomyelitis according as they were caused by the staphylococcus albus, aureus, the streptococcus, etc., and with the light thrown upon one of these forms by the authors, he would feel bolder in treating them according to principles of advanced surgery.

Dr. Gibney related his experience with cases of what clinically seemed to have been streptococcus osteomyelitis, in one of which he was surprised, owing to the low condition of the patient, to find that she recovered after several operations on the long bones.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, December 16, 1891.

Egbert H. Grandin, M.D., Chairman.

Ovary Containing a Bone.—Dr. H. C. Coe presented a small bone which he had found in an abscess of an ovary removed from a woman who had suffered a number of years from extreme local pain. He was unable to say whether the specimen was in a commencing dermoid or whether it had been present a long period.

Angioma of the Liver.—Dr. H. T. Hanks related a case of what had been supposed to be a cancerous growth from the liver, but puncture with the needle withdrew thin venous blood. Exploratory laparotomy was then performed, and the tumor was found to be situated on the lower lobe of the liver, of large size, extending across the median line a considerable distance, and on being punctured thin venous blood came forth freely. The line of demarcation between the healthy and diseased tissue was pronounced. The abdomen was again closed, and further treatment consisted in the use of galvanism, one large sponge electrode being pressed well up under the ribs against the lower surface of the tumor. On one occasion galvano puncture was resorted to, but was not repeated for the reason that the tumor had already diminished about two-thirds in size, and the patient had become able to do her housework without inconvenience. He added that a case was reported once by a member of the New York Obstetrical Society in which the diagnosis of angioma of the liver was made and the patient completely recovered.

Intra-ligamentous Rupture of Ectopic Gestation, and Its Expectant Treatment.—Dr. George W. Jarman read a paper with this title. He believed with Tait that where rupture had occurred into the broad ligament, being extra-peritoneal, it was highly improbable that secondary rupture and hemorrhage would take place into the peritoneal cavity. Tait had never seen a case of secondary rupture into the peritoneal cavity. This being true, the author saw no necessity for exposing the patient to the dangers of laparotomy after intra-ligamentous rupture. Expectant treatment was advised. Should any accident or symptoms arise, one could hold himself in readiness to interfere with the knife. He had met with two cases in which the symptoms and physical signs were those of intra-ligamentous rupture, this diagnosis being further confirmed by the patients not having for a long period, or never, borne children; the existence of uterine trouble, then the occurrence of menstrual and other changes pointing to pregnancy, and finally by the occurrence of sudden pain and fainting. The treatment was entirely expectant, the patients being placed in the recumbent posture and compelled to maintain it for a sufficiently long period. Both of them had made a satisfactory recovery, and gradually the tumor had nearly or quite disappeared. As to the source of the hemorrhage, he thought it came more from the open sinuses than from the arteries and veins.

Dr. Coe had often wondered why so many authors had been silent as to the source of the hemorrhage. It did not seem probable that it could all come from ruptured tubal arteries and veins. He had never been able to convince himself in any case that secondary rupture had taken place into the peritoneum. He had seen one in which the escape of blood was very great, amounting to at least three pints, being extra-peritoneal and dissecting up along the spine. He did not see why there should be any special danger where early rupture had take place in the broad ligament.

Dr. Hanks thought there was no danger from secondary rupture into the peritoneal cavity in intra-ligamentous rupture, yet we could not be quite sure, he said, that after treatment by the expectant plan, or by electricity, there would not be need for further attention. For instance, one patient had had to come a second time from Texas, where he removed a hæmatoma from the site of the former rupture in ectopic pregnancy.

Dr. Cregan said a patient had been received into a hospital where he was interne who gave a history of ectopic pregnancy; rupture just before she entered; tumor felt distinctly on the left side per vaginam. She was kept quiet; virtually nothing was done; at the end of three weeks she was fully convalescent. Some time afterward she was operated upon for rupture of a pyosalpinx on the opposite or right side, and examination of the left tube then showed some thickening of the broad ligament and a scar, which seemed to confirm the previous diagnosis of tubal pregnancy and rupture on that side.

Dr. Locke presented a volume of "The Philosophical Transactions," which contained a very good illustration of a case of ruptured tubal pregnancy which had occurred in 1817.

The Chairman was prepared to admit that cases heretofore reported as representing secondary rupture into the peritoneum after rupture in the broad ligament were cases in which there had been an error in diagnosis. The blood would dissect up the membrane, travelling in the direction of least resistance, before it would cause secondary rupture through the broad ligament into the cavity.

Suppurative Oöphoritis.—Dr. H. J. Boldt read a paper on chronic suppurative ovaritis, the principal part of which was devoted to a description of the minute pathological changes. He differed from those who held with Cohnheim that the inflammation and suppuration were based on an emigration of colorless blood-corpuscles. Briefly stated, it was the author's conviction that all the constituent tissues of the ovary, including the fibrous, epithelial, myxomatous, and vascular structures, participated in an active manner in the production of inflammatory corpuscles which, when broken asunder, furnished

the pus-corpuscles. The paper was illustrated by drawings of the inflammatory changes as they had taken place in the different structures in the several cases which had come under his observation.

Passing to the clinical considerations, he said true ovarian abscess of non-puerperal origin was very rare, though not so rare as some authors seemed to believe. Most published cases had been connected with the puerperium, were tubo-ovarian abscess or ovarian cystomata, and therefore not true ovarian abscess. It was evident from what he had stated regarding the pathological anatomy, that a true ovarian abscess could not attain a great size, seldom larger than an English walnut, and very seldom, indeed, larger than a hen's egg. A microscopical examination was necessary to a positive diagnosis.

The prominent symptoms of chronic ovarian abscess were pain in the region of the ovary, which might radiate to the hypogastric or sacral regions. It was dull, sometimes sharp and lancinating, and differing from that connected with salpingitis in that it was not modified by menstruation. Reflex nervous symptoms, such as headache, etc., might be present. Physical examination revealed a condition resembling oöphoritis, peri-oöphoritis, and peri-metritis, from which it could not be positively differentiated. This chronic suppurative ovaritis, as the author would have it called, might extend over a long period. When an acute process became engrafted upon the chronic, the patient had slight chills at irregular intervals, the pain was more severe, and limited more strictly to the ovary, the ovary increased in size, fluctuation was more or less prominent, the temperature and pulse were enhanced.

Regarding treatment, this was often continued a long time locally, while hesitating about a positive diagnosis. Where the symptoms already mentioned continued, although perhaps slightly modified by treatment, the abdomen should be opened, and if suppurative ovaries were found they should be removed. If the abscess walls were thin, or the adhesions were such as to endanger rupture during enucleation, it should first be aspirated. If it were adherent to the floor of the pelvis, it should be opened per vaginam, drained, and treated like other pelvic abscesses. This could be done without danger after the abdomen had once been opened.

If some of the virulent pus entered the abdominal cavity it rendered the prognosis grave, otherwise it was favorable.

Some of the points made in the discussion, which was participated in by Drs. Edebohls, Coe, Jarman, Hanks, Goelet, Waldo, Buckmaster, and the Chairman, were the possible origin of ovarian abscess in the gonococcus or other germs which reached the ovary not by way of the tube, but through the lymphatics, from the intestines, etc. It was generally conceded that true ovarian abscess, as it had been described in the paper, was of small size, situated well up, and unless unusually located through adhesions, could not be treated through the vagina.

Intubation and Tracheotomy.—In a report of these operations done at the Boston City Hospital, Drs. Prescott and Goldthwaite (*Boston Medical and Surgical Journal*, No. 27, 1891) draw the following conclusions: Three hundred and ninety-two cases of intubation, and 139 cases of tracheotomy have been reported, with a mortality-rate of 79.59 per cent. in the former, and 88.5 per cent. in the latter; 2,815 cases of intubation, and 23,941 cases of tracheotomy have been collected and analyzed, showing comparatively no difference in the mortality-rate of the two operations. The results depend more upon the nature of the epidemic than upon the operation. With intubation the results depend more upon the skill and experience of the operator than with tracheotomy. Thirty-seven cases were seen at least a year and a half after recovery from intubation, with perfect voice, and with nothing that would indicate any ulceration from pressure of the tube.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PATHOLOGICAL SOCIETY—DISCUSSION ON THE MORBID CHANGES FOUND IN THE MAMMA IN ASSOCIATION WITH CANCER—INFLUENZA AGAIN ACTIVE—DEATH OF MR. BERKELEY HILL—THE COLLEGE OF PHYSICIANS AND ITS LICENSE

LONDON, January 9, 1892.

THE first meeting of the Pathological Society for the present year took place on Tuesday evening last. Mr. Charles Morton presented a specimen of tuberculous ulcer of the tongue with sections, showing bacilli. Dr. Rolleston showed one of sarcoma of the duodenum. The interest of the evening, however, centred on the pathology of mammary carcinoma, on which subject two papers were read. The first of these was by Mr. Raymond Johnson, and gave an account of an investigation which the author had made, as to the pathological conditions in the breast found in association with carcinoma. Mr. Johnson had endeavored to ascertain whether pathological evidence could be obtained, indicating the propriety of the complete removal of the organ in cases of carcinoma. He had examined the condition of the mammary tissue in numerous cases, both by the naked eye and by the microscope. Small cysts in the breast-tissue were not uncommon, but he found no evidence that their relation was more than accidental; he suggested that such cysts might arise as the result of the blocking of the ducts by the growth of the tumor. In many cases the microscope showed morbid changes when examination with the naked eye gave no evidence of disease. Thus, in one case, it was found that there was invasion of remote parts of the breast through the lymphatic spaces, as in the infiltrating variety of the disease. It was more common to find proliferative changes in the epithelium of the acini; the latter were somewhat dilated, and more or less blocked by masses of swollen, faintly-staining cells which often had indistinct outlines. These changes were well seen in a small indurated area excised by Mr. Godlee from the centre of the breast of a woman forty years of age. The condition was probably one of chronic inflammation, and there were no signs of tumor formation. Mr. Johnson also showed specimens showing these changes in breasts the seat of carcinoma, and a specimen from the breast of a lady, whose opposite breast had been removed for carcinoma by Mr. Berkeley Hill, several years previously. Mr. Johnson suggested that these proliferative epithelial changes probably stood in the same relation to cancer of the breast as chronic superficial glossitis did to cancer of the tongue, viz., that they constituted a precancerous condition. He summarized as follows the conditions found in the breast in association with carcinoma: gland tissue apparently healthy, gland tissue atrophied and with a large admixture of fat and fibrous tissue, chronic proliferative epithelial changes, infection of the gland through the lymphatics, cystic changes, and lastly, the presence of simple tumors. The author thought his observations pointed to the conclusion that, so far as possible, all the gland-tissue should be removed in excising a cancer of the breast, specimens were exhibited showing fragments of breast-tissue left behind in the usual operation of excision, and others showing that such fragments might, in some cases at least, be the starting point of recurrent growths.

Mr. Cecil Beadles then read a paper in which he gave an account of the histological changes in the breast found in association with glandular carcinoma, based on an examination of about one hundred breasts which had been removed for carcinoma. Such breasts he said, were never in what might be called a normal state, but it was doubtful to what extent the conditions found were dependent on the presence of cancer. Mr. Beadles referred to the frequency with which small carcinomatous nodules might be found at a distance from the larger growth, and hav-

ing no connection with it, and passing on to the consideration of the changes found in the stroma of the breast lobules, said that there might be seen in different cases all the stages of what was usually described as "chronic interstitial mastitis," viz., small round-celled infiltration, a stroma formed of young connective-tissue cells, and one of a dense fibrous tissue—the latter either associated with atrophy of the gland acini, or with the formation of cysts. There was often also a marked proliferation of the epithelium within the acini, with perhaps degeneration of the central cells. The author also described a peculiar change found in the gland acini of some breasts affected with malignant disease, consisting in the increase, combined with great irregularity in size, of the epithelial cells—some being very large and indistinguishable from malignant cells, and often associated with degeneration of other cells. This condition might be looked upon as a stage between simple adenoma and glandular carcinoma—in fact, as commencing malignant disease. A papilliform change sometimes found in the epithelium of the ducts was next described; this presented itself in two forms, and the process of degeneration could be traced in adjoining spaces of both the stroma and the epithelium. In concluding his paper, Mr. Beadles said he believed that the changes which he had described in the gland acini were independent of the primary growth, and were probably produced by the same cause as the latter. In his experience, the direct infection of the breast through the lymphatics was extremely rare, except in the immediate neighborhood of the growth. These changes in the epithelium might account for recurrence of the disease in some cases, so that very great care should be exercised in the removal of all traces of the mammary gland.

The President (Sir George Humphry) said it was usual to find cancer localized in one spot, yet its return in a distant part was common. This fact suggested that in many cases disease might be lurking in a distant part of the gland, though it was not to be detected by any ordinary method of examination. He had often noticed that after the removal of a breast for cancer there would happen a recurrence in tissue which was not apparently mammary; this happened too frequently to be accounted for by the idea that in every case portions of breast tissue had been left behind. He remarked that Mr. Stiles, of Edinburgh, had found that much of the connective tissue between the breast and the axillary glands possessed a glandular structure which might of itself be the site of recurrence. He agreed that mammary cysts had no particular relation to cancer. He remarked that the mammary glands were peculiar organs—they might remain functionless through life, they might be repeatedly functional for limited periods, or one organ might remain functionless while the other was used; he thought it would be worth inquiry as to which of these three conditions was the more frequent precursor of cancer.

Mr. Bowlby thought many of the changes described had nothing to do with cancer; he had found similar changes in many breasts taken from persons of middle age not affected with cancer, and he thought that, at the most, such changes would only predispose to cancer. A cancer growth often spread a considerable distance beyond its apparent limits, and the breast tissue in these subjects was so little in depth that a small cancer nodule would lie in relation with both the skin above and the pectoral fascia below. He asked the authors how far from the cancer nodules these changes were found. Their papers seemed to suggest that secondary growth—and at a part of the gland distant from the primary focus—was almost sure to follow, but he did not think this result was so very common. At St. Bartholomew's Hospital it was the practice of some of the surgeons to remove the growth only, and leave the gland if the growth were limited to the axillary border of the latter. Where this had been done, if recurrence followed, it was usually not in the breast at all but in the axillary glands.

Mr. Watson Cheyne said he had examined Mr. Stiles's specimens and agreed with his conclusions. He felt convinced that cancer spread by growth along the course of the lymphatics rather than by continuous growth along the ducts. The lymphatic plexuses in the mamma were so free that he did not feel justified in adopting partial amputation, even when the growth seemed to be limited to the axillary border. It was important always to remove the pectoral fascia, for lobules of the gland penetrated it and lymphatic vessels traversed it. He had examined a large number of small nodules of recurrent growth, and found that they were, in most cases, embedded in a bit of breast tissue which possessed healthy acini; this again pointed to lymphatic infection.

Mr. Raymond Johnson said he was at present engaged in examining a number of specimens of breasts of women between forty and forty-five, and, though he had found changes, these were not nearly so marked as in several of the carcinoma cases. Where he had referred to tissue examined from a part of the gland remote from growth he had meant that the specimen was taken from the opposite hemisphere of the gland at a distance of two or three inches from the primary growth. He had found the changes which he had described in many, but not in all, of the cases he had examined.

Influenza has become prevalent again over a great part of the kingdom, and has appeared in most parts of the metropolis. Thirty-seven deaths from the disorder were registered in London last week. Generally speaking, however, the disease appears to be of a milder type than in the previous epidemic. Doctors and nurses have, nevertheless, been in great request, and I was informed a day or two ago that no female nurses whatever could be obtained from the leading nursing institutions, owing to the number of patients requiring their services.

The death is announced of Mr. Berkeley Hill, Senior Surgeon to University College Hospital and Professor of Clinical Surgery in the College. Mr. Hill was also Surgeon to the Lock Hospital and had a considerable reputation as an authority on venereal diseases, on which subject he published several works. At the time of his death he was one of the two Vice-Presidents of the Royal College of Surgeons.

The Royal College of Physicians has obtained a legal opinion favorable to its claim that the License of the College is by itself an adequate qualification entitling the holder to register under the Medical Acts.

THE DOSE PARALDEHYDE.

To the Editor of the Medical Record.

Sir: In your issue of December 19, 1891, appears, under the heading "A Large Dose of Paraldehyde," a short article by J. Noer, M.D., of Stoughton, Wis., which I venture to criticise.

To be brief, the doctor states that he prescribed two and one-half drachms of paraldehyde for his patient, to be given in 15 minim doses "every half hour until sleep was produced." But his "reckless" patient took it all at one dose, and bromide of potassium was given as an antagonist. While admitting two and one-half drachms of paraldehyde to be a large dose, it is decidedly not an alarming dose, or one to produce alarming symptoms, and I think the doctor is in error when he ascribes the "delirious tendency and a little quickening of the pulse" to the paraldehyde. I also admit that in theory, as laid down in our text-books, one drachm of paraldehyde is the maximum dose, yet in practice I have seldom seen that dose produce sleep.

In a practical experience of nearly four years in the continuous use of paraldehyde, I have yet to meet with a case in which a dose of two and one-half drachms produced delirium or any untoward quickening of the pulse. Cervello says "paraldehyde affects the cerebrum, spinal cord, and the bulbus successively, abolishing the reflexes,

causing anæsthesia by anæmiating the brain and cord. It is eliminated by the lungs and is not a cardiac poison." Hare, in his "Practical Therapeutics," says "paraldehyde kills when taken in overdose by respiratory failure, but is not so depressant to the heart as is chloral," but he neglects to state a quantity which might be considered a poisonous dose.

I use paraldehyde continuously and almost exclusively, because in my opinion, based upon a study of its effects in several thousand administrations, it is the better and safer hypnotic. It certainly is not pleasant to take, and the odor can be detected in the breath for nearly twenty-four hours after admission, even from so small a dose as twenty minims, but it has no unpleasant nor depressing after-effect, and produces a more natural sleep than any other similar drug with which I am acquainted. Gastro-intestinal disorders contra indicate its use, and I should say its action on the heart is *nil*, even where there is organic lesions. I invariably exhibit two drachms of paraldehyde as an initial dose, and then increase to two and one-half drachms if necessary. I have given in special cases three and one-half drachms of this drug with no other than a quiet sleep-producing effect, but so large a dose I do not consider safe, and it must be used advisedly. I repeatedly give two drachms, followed in one to two hours by a similar dose should the first not be effective, and I believe it to be the consensus of opinion among those who have used paraldehyde and studied its effects that two drachms is the ordinary or proper dose.

I have seen but one case of paraldehyde habit—an old lady over seventy years of age, who, broken down physically and mentally and a victim of morphia, had paraldehyde substituted. I believe the danger of forming a paraldehyde habit is so small as to be hardly worthy of consideration.

In conclusion, I would refer Dr. Noer, should this meet his eye, to an article entitled "A Clinical Study of Paraldehyde and Sulphonal," by C. M. Hay, M.D., published in the *American Journal of the Medical Sciences* for July, 1889, which is an exhaustive essay on the relative merits of the two drugs, and may be read by any one with profit and pleasure. Certainly I must infer from Dr. Noer's article that his experience in the use of paraldehyde has been extremely limited.

Yours very truly,

ELIOT GORTON, M.D.,
Second Asst. Physician, State Asylum for the Insane.

MORRIS PLAINS, N. J.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I was astonished to read in the MEDICAL RECORD of December 19th last the letter of J. Noer, M D., on the above subject. My surprise was not so much from the strangeness of the case itself as from the limited knowledge one seems to have of the effects of this drug. For the past year I have been in the habit of nightly giving doses of paraldehyde of not less than four to ten grains in a dose, repeated after a couple of hours if the desired effect has not been obtained, and I have never met with any accident from its administration.

W. M——, a patient, arrived at our Retreat, in the beginning of August last, in a state of intoxication. He was much excited, and as I had known him for some time, I administered a dose of one ounce of paraldehyde in water, which I was obliged to repeat in an hour's time, the first dose having been perfectly useless in procuring sleep. Two hours later the patient was still awake, but having given two such large doses, I did not think fit to risk giving any more. At midnight, three hours after I had given the second dose, I found my patient sleeping tranquilly. At 7 the next morning he awoke, drank a little milk and lime-water, and again slept until 10.30 o'clock. He then awoke, and recalling his previous day's debauch, was in a very remorseful mood, and asked me for more paraldehyde, saying: "Let me sleep and forget." I refused, needless to remark; I did not consider it necessary to give any more.

To my great surprise the keeper in charge showed me a four ounce vial found in the patient's room labelled "Paraldehyde." The druggist who had sold the drug to this patient told me some days later he had given four ounces on the same day he arrived at the Retreat. Therefore the man had taken six ounces of paraldehyde! And he had slept, with intervals of awakening, only about eleven hours.

This case I believe to be an exceptional one. But I am confident that more than four grammes can be given without any risk, and that very often this dose is an insufficient one.

P. V. FAUCHER, M.D.,
Resident Physician to Belmont Retreat, Quebec, Can.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of December 19, 1891, I reported a case where a man on the verge of delirium tremens took ten grm. (℥ ijss.) of paraldehyde with no untoward symptoms. I regarded this as a very large dose. A medical gentleman has since written me that this is not an unusual dose, and quotes Bartholow as giving a dose at from ℥ j. to ℥ ijss. Dr. B. quotes Bartholow as follows: "To succeed it (paraldehyde) must be given in sufficient quantity, the maximum dose mentioned above (℥ ijss.) has often been given without any after-trouble of any kind, and has often proved necessary."

This is certainly news to me, and if it be in accord with facts, is of importance, since paraldehyde is a new drug that has been comparatively little used.

James C. Wilson[1] says "paraldehyde in doses of half a drachm to one drachm repeated at intervals of two or three hours until sleep is induced."

H. C. Wood[2] gives the dose as a hypnotic at one drachm; he quotes Kraft-Ebing as having given three drachms per day for spinal accessory spasm.

The "Annual of Medical Sciences" for 1891 (vol. v., p. 117) gives the average dose at 1 drachm. Flint reports 35 cases, dose ranging from 60 to 90 minims.

C. Conquil[3] says that "abroad and in Italy doses of ℥ j. ℥ jss., and ℥ ij. a day are given; Dujardin-Beaumetz gives 30 grains in order to suppress the initial period of excitability which follows on larger doses.

Desnos claims that if hypnotic effects are not obtained with from 45 to 60 grains, it is useless to push it.

H. A. Hare[4] gives the dose at from 30 to 60 minims, if I remember correctly.

S. Ringer[5] says: "The narcotic dose for an adult is from 30 to 50 minims."

I have never ventured to give more than 60 minims at a dose, and have often had good results with much smaller doses. If ℥ ijss. can be given with impunity, it would be interesting to hear from a few cases in which this quantity has been administered in one dose.

J. NOER, M.D.

STOUGHTON, WIS., January 10, 1892.

Strontium Salts have been shown by Laborde (*Brussels Academy of Medicine Reports*) to be valuable and non-poisonous therapeutic agents, being better tolerated than the salts of potassium, and twice as active, besides having antiseptic and germicidal properties. Constantin Paul has, however, pointed out in a timely manner that the drug is difficult to obtain in a pure state and almost always contains salts of baryta, which are very poisonous. Accidents have already happened from the use of iodide of strontium.

A CRITICISM ON MEDICAL TEXT BOOKS.

To the Editor of the Medical Record.

Sir: It is the intention of the writer to say something conducive to the relief of young practitioners from an embarrassment which is probably experienced by every conscientious person entering upon the practice of medicine.

It is presumed that the "young physician" has enough knowledge to know in most cases whether or not he has a serious case to treat. Suppose he has a severe case to treat, he sits down to read it up. Then it is he finds how rich medical literature is in indefiniteness. How non-committal is his book. One therapeutic measure he often finds is *sea bathing*. He is in a town hundreds of miles from the sea-shore. It is perhaps mid-winter and the patient poor. All other therapeutic measures in this particular case are put down in an apologetic manner that is highly discouraging. Did it ever occur to medical authors how very few people are ever able to see the ocean, much less bathe therein? Will some one of our prominent authors volunteer to write a text-book of medicine and shun sea-bathing as a therapeutic measure? The writer believes it to be less serviceable than "tuberculin." It is difficult enough for people to get money with which to pay the doctor, let alone going to the sea-shore, and more often than otherwise coming home to harass the home doctor all winter and leave for the sea-shore in the spring. What the puzzled doctor wants when he reads, is a book written by a man who has the courage of his own convictions and a smattering of perspicuity in transferring the same to paper.

Another glaring defect in nearly every text book of medicine is the lack of details. The *pathology* is apt to be rich in details. However, the friends of a corpse do not appreciate his perfection as a subject of pathological investigation. We want details, and *detailed details*, upon the whole of any disease under discussion. How few inexperienced physicians know how to arrange their treatment to meet the varying stages of a disease. Particularly an acute disease requiring prompt action and no faltering. For lack of details in his whole medical education, he charges on the enemy too late.

Diseases of children is another neglected subject in our medical schools. The clinical teaching in this department of our colleges is almost a farce. The students spend their time in hospital wards examining adults. They see a few children in the "out door clinic," and then mostly such cases as can be carried through the streets. The student catches the mumps or the measles more often than he does a practical hint on the management of a sick child.

Another thing which the professor of materia medica and therapeutics does not have time to teach, is why he gives a maximum dose to one patient and a minimum dose to another, using in each case the same drug. The difference in physique is not always the reason. Little is ever said to students about the difference of susceptibility of different individuals to the action of a drug. Much is said about "idiosyncrasy." The peculiarity known as "idiosyncrasy" is more often the result of habits or perversity of the patient, which the physician fails to detect and so accepts the situation, and names it an "idiosyncrasy."

Climate very largely influences the action of drugs. Provincial habits of living also. A student educated in medicine on the Atlantic coast is taught to prescribe on that coast, and is nearly lost on the Pacific coast. A climate having a wide range between the summer and winter temperatures always furnishes patients who respond most quickly to the action of drugs; while a climate of a more constant temperature furnishes the converse. Let our teachers of medicine be more detailed in their teaching, if they have to cover less ground. Let the course of medical education be prolonged to meet the requirement.

THE HARM OF NAUSEATING EXPECTORANTS IN THE BRONCHITIS OF CHILDREN.

To the Editor of the Medical Record.

Sir: I have not had time to consult the literature on this subject, and therefore I may be going over a "thrice told tale," but I feel that the subject is important enough to be repeated, as a talk with the profession will convince anyone that nauseating expectorants in the bronchitis of children still hold a high place in the minds of the majority. I believe many children are made seriously ill, probably carried beyond the point of recovery, by these nauseating expectorants, which are generally most harmful in the treatment of the disease in children under four years of age. I will state here that I do not include that fatal disease, capillary bronchitis, but that my remarks are confined to bronchitis of the larger bronchial tubes—a very common disease among children—particularly the children of the working classes, whose parents are entirely ignorant or indifferent to the laws of hygiene. Nauseating expectorants not only depress the system, but they lessen the desire for food, thus rendering it more difficult to keep up the all-important nutrition. For the disease being a limited one, we must first look to the strength of the child. A liberal supply of nutritious food and stimulants enters largely into the treatment. The fever must be kept down by quinine—no drug will take its place. The mild alkalies do best as expectorants, and when I add to this list of remedies belladonna, I think we can cure most cases of bronchitis of the larger tubes found in children. Nauseating expectorants can only do good at some critical moment when the tubes are found to be rapidly filling up, and here belladonna proves a most valuable prophylactic; for if it has been used, the case will be rare in which the mucus becomes excessive; and if the strength of the child has been kept up, nature will, at the proper times, relieve the overfull tubes by vomiting. The mucus can be kept loose in the tubes by allowing the child to inhale steam, say every two hours. Vomiting is oftener brought on by the spasmodic element in the cough, than by an effort to rid the tubes of mucus; and belladonna in a great measure controls the spasms, at the same time strengthening the heart and respiration. My remarks on bronchitis are equally applicable to the rather insiduous form of broncho-pneumonia occurring during whooping-cough. Let us hope that the use of nauseating expectorants, in the treatment of bronchitis in children, will only find a place in some few exceptional cases.

Philip S. Roy, M.D.

141 I Street, N. W., Washington, D. C.

Feigned Hæmophilia.—Dr. Unverricht showed a patient who for several months had bled from the ears, nose, and eyes, and had frequent hæmaturia. The right side of the body showed paralysis, and there was hemianæsthesia and hemianopsy. At a time when hæmaturia was supposed to be present, the urine was drawn off under chloroform narcosis and found normal. At the same time a needle was found adroitly concealed in the hand. This was replaced before consciousness was recovered, and shortly afterward another bleeding from the ear occurred, but this time the puncture of the needle was plainly visible in the external meatus. It was further demonstrated that the blindness and deafness which the patient claimed were only assumed. The opinion is advanced that such instances of bleeding from the skin, eyes, ears, etc., are always due to more or less clever simulation, and that the cause can be found if persistently looked for.—*The Lancet.*

To Remove Rust from Iron.—Scour with a mixture of one part each of cyanide of potassium and soft soap, and two parts of whitening made into a paste with a little water; then wipe off carefully and apply oil to prevent further action.

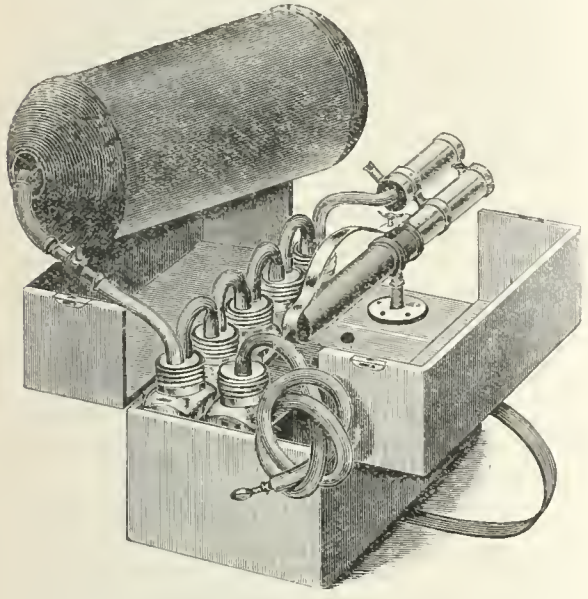
New Instruments.

AN IMPROVED FORM OF PORTABLE APPARATUS FOR EVOLVING AND PURIFYING OXYGEN.

By SAMUEL S. WALLIAN, A.M., M.D.,

NEW YORK.

The use of oxygen, both by physicians and surgeons, has become so general and so fairly indispensable within the past decade that the necessity for convenient and efficient forms of generators for its prompt evolution in a pure state and in reasonable quantities has become a question of considerable importance. Until recently Limousin's apparatus, made by Galante, of Paris, has been considered the leading one for medical use. It is now conceded that those of American manufacture have relegated the



French device to the days of the stage-coach. For several years this market has been supplied with a very effective and convenient small apparatus, with a capacity ranging from six to twelve gallons at an operation. I have recently devised a modified form which combines some advantages not heretofore deemed feasible in a portable apparatus, viz., great compactness with considerably increased working capacity.

The accompanying illustration gives a general idea of this improved form of apparatus.

Instead of the usual form of containing case, the top or cover is divided vertically, each half opening toward its respective side and being held, when open, at right angles to the case proper by means of stop-hinges, the object gained being a protection of the lighted lamp from air-currents which, in an open situation, sometimes retard the progress of an operation. There are compartments accommodating six wash bottles and an inhaling bottle; or one of them may be utilized as a convenient receptacle for extra retorts, or for a bottle containing alcohol.

The retort-socket or standard is fitted to accommodate a duplex cylinder cooler and two sizes of retorts, the smaller one affording about fifteen gallons and the larger one twenty-five gallons of oxygen at each operation. The retorts are of brass, and are attached to the socket or nipple by a friction joint, screw connections having been found fatally defective in practice. The smaller retort is self-supporting during an operation, while the larger and longer one is firmly held in position by an adjustable arm or support made of tempered brass and held in position by a thumb-screw.

Notwithstanding the increased capacity of this instrument, the case, having storage capacity sufficient to accommodate all accessories needed for its immediate use, measures but $9 \times 10\frac{1}{2} \times 14\frac{1}{2}$ inches, a not at all unwieldy size for convenient transportation.

The cooler, which is designed to cool the escaping gas sufficiently to prevent overheating the rubber connections, is attached in a horizontal instead of the usual upright position when in use, with a view to greater efficiency. When from rapid or prolonged use there is any tendency to excessive heat, it can be promptly obviated by applying a wet cloth or sponge to the prone body of the cooler.

The wash-bottles are fitted with an ingenious form of hard-rubber pulverizing tubes, and with rubber stoppers or corks having a projecting lip or flange which, by means of a metal screw-cap, is accurately compressed against the mouth of the bottle, thus affording a double and very effectual safeguard against leakage. Using two alkaline and two nitrate of silver solutions, in connection with a filtering bottle of absorbent cotton, the passing gas, broken into minute bubbles by the pulverizing tubes, is thus much more perfectly washed and purified than has heretofore been accomplished. The filtering-bottle is a duplicate of the other wash-bottles, except that instead of containing a corrective solution it is closely packed with absorbent cotton, which has been found to effectually intercept certain sublimed products of the decomposition of chlorate of potassium, traces of which unaccountably escape detention in the wash-bottles proper.

Heat for evolving the gas is applied by means of spirit-lamps, two of which are provided, so that, especially when using the larger retort, an exhausted lamp may be instantly replaced by a full one without interrupting the operation. For use in these lamps, which are made on the argand principle, are packed with asbestos fibre, and have a perforated double bottom, deodorized wood-spirit answers perfectly, while it costs about one-half as much as ordinary alcohol.

The accessories provided with each instrument include two pure gum-bags holding twelve to fifteen gallons each, inhaling bottle, connecting tubes, and mouth-pieces for inhaling purposes. When it is desired to intensify the slight degree of ozonization always present in freshly-evolved oxygen, the sixth or extra wash-bottle is to be about half filled with a 15-volume solution of the best obtainable hydrogen dioxide. It is then to be used as an extra inhaling bottle, by being connected with the rubber gas-holder, between the latter and the regular inhaling bottle. In this case the inhaling bottle proper may be used entirely empty, to prevent any spray of the solution from penetrating the inhaling tubes. The only brand of hydrogendioxide which has fully met the requirements as to strength and stability is that prepared by the Oakland Chemical Company, of this city, and known as the "O. C." brand.

THE TREATMENT OF PNEUMONIA.[1]

BY J. L. GREENE, M.D.,

RED CLIFF, COL.

IN the section where I have practised medicine for several years past, at an altitude of seven thousand to ten thousand feet above sea-level, pneumonia is very prevalent and very fatal. We have a form of the disease called "congestive," or "high line," pneumonia, which often kills the patient in a few hours, and if relief is to be obtained at all it must be speedy. Clinical observation of such cases convinced me that the patient wanted oxygen, and wanted it rapidly and abundantly. In casting about for a source of supply, it occurred to me that peroxide of hydrogen ought to meet the indications, and I tried it; and clinical experience soon proved that it was exceedingly valuable for controlling congestive pneumonia, croupous pneumonia, membranous croup, and in fact any affection in which it is desirable to dissolve secretions in the lungs or throat. It appeared to be quickly absorbed into the blood, and the oxygen exhaled through the lungs, dissolving and carrying off the morbid secretions with the expired air. I commenced its internal use in 1888, but at that time there was very little literature on the subject, and I did not use it freely until I had felt my way. The authorized dosage was one to three teaspoonfuls, three times in twenty-four hours. Even after doubling and trebling the frequency of the dose, the results were not as good as at present, though I ceased losing cases of pneumonia. The patients might be very ill, but they did not die. I was previously using the drug as an antiseptic in surgical cases, and had observed its power as a germicide, and being an adherent of the germ-theory as regards pneumonia, I ventured to hope from the first that it might destroy the specific germ, and hence used it freely in all forms of the disease, whether dyspnœa was present or not. My experience has convinced me that it does destroy the germ, for the disease, instead of going on to a crisis, will, when this treatment is begun early in the case, commence to fade away in from twenty-four to forty-eight hours, and no crisis will occur at all. However, cases of acute lobar pneumonia, without dyspnœa, which are not treated till the disease has made considerable progress, will have a modified crisis. Any line of treatment is liable to be at a disadvantage in this form of the disease, as the patient and his friends will sometimes consider it only a bad cold, with perhaps a touch of pleurisy, and will not call medical assistance till the disease is strongly entrenched. But in congestive and croupous cases the dyspnœa is so distressing and alarming that the physician is called early. I believe this is the reason why it sometimes appears that this treatment is less efficient and prompt in the lobar and typhoid, than in the congestive and croupous types.

The dosage necessary to be efficient is something appalling to a practitioner not accustomed to it. The object is to saturate the patient with the medicine as soon as possible, and then to keep it exhaling through the lungs. An adult will bear half a teaspoonful of Mallinkrodt's preparation in two teaspoonfuls of cold water, or from one to three teaspoonfuls of Marchand's, Drevet's, Herf & Frerich's, or any other of the fifteen-volume solutions, well diluted, once in three to five minutes for an hour or more. The same dose may then be given half-hourly, or hourly, till convalescence is established; and it should be crowded as at first at any time if dyspnœa returns. There is no ill effect from it except occasional nausea and vomiting, apparently from mechanical irritation of the stomach. In such cases it is well to decrease the dose a little, and increase the amount of water given with it. But in cases of young children, especially infants in arms, it should be crowded till vomiting is induced, to remove accumulations which they are unable to throw off by expectoration, and which may not be dissolved rapidly enough by the oxygen. Children, even but a few weeks old, bear it remarkably well, and will take proportionately larger doses than adults. It also seems to me a clinical fact, that nearly all cases progress more satisfactorily if treated for a day or two at the outset with rather large doses of hydrargyrum cum cretâ, or hydrargyri chloridum mite, and that typhoid types should have frequent doses of oleum cinnamoni in addition to the peroxide of hydrogen.

Formerly, when treating pneumonia on the expectant plan, and believing the common fallacy that no treatment could cut short or abort the disease, I was opposed to the use of antipyretics of the coal-tar series, and as late as July 20, 1889, in an article published in the NEW YORK MEDICAL RECORD, outlining the present treatment, I expressed the opinion that they were of no benefit. Nor would I now advocate their use in the expectant treatment. But further experience has modified my views of such antipyretics when used in connection with this new line of treatment. It appears to be an advantage to bring the fever down and hold it down, depending on the oxygen to destroy the germs rather than letting them burn out with the fever. For a year or more I have been accustomed to control the fever during the few days it persists, with acetanilid, or phenacetin, using a full dose at first, and small repeated doses afterward. I have not been able to discover any ill effects from it. There is nothing in this treatment to prevent meeting any complication with rational measures, but there is far less use for digitalis, or other heart tonics, than with the expectant plan.

I have, from time to time, called the attention of practitioners to this method of treatment, but with the exception of several Denver physicians, it has appeared to be outside their zone of lucidity. It was either too simple to be seriously thought of, perhaps, or was not tried heroically enough to produce results. Indeed, certain practitioners, without making themselves acquainted with the treatment, have not hesitated to account for its visible success by insinuating that the cases were not pneumonic. However, with the pathognomonic rusty-colored sputa present, my confidence in the diagnosis has not been greatly disturbed.

Since 1888 I have treated 157 cases which were not of doubtful diagnosis, besides others which I believe were pneumonic, but which were taken in hand almost with the inception of the disease, and cut short before the development of pathognomonic symptoms. Of the 157 undoubted cases, 154 made good recoveries; of the three who died, one was an infant a few weeks old, a long distance in the country, and past recovery when first seen; another was a young lady in an advanced state of phthisis pulmonalis. She died of pulmonary hemorrhage, while convalescent and able to sit up after the attack of pneumonia; and the third was a middle-aged woman who had

[1] Read before the Colorado State Medical Society.

a valvular disease of the heart, and had been under my care for that trouble most of the time for two years previous to the pneumonic attack. She could not have lived very long, but her death, as well as that of the consumptive, was undoubtedly hastened by the attack of pneumonia. The recoveries include very young children, aged persons, drunkards, and persons with constitutions impaired by excesses, as well as the robust and vigorous.

In conclusion, I would say that while this treatment has been almost phenomenally successful in my hands, there are other members of this Society who have used it to some extent, and whose experience will go to confirm what I have said. I believe if the members of the Society who listen to this paper will give the matter a fair consideration, the mortality from pneumonia will be materially lessened in our part of the country.

THERAPEUTIC RESULTS OF DIRECT ELECTRIZATION OF THE STOMACH.

By MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY AND INSTRUCTOR IN CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

(Continued from page 121.)

V. *Chronic Gastric Catarrh with Beginning Atrophy of the Mucous Membrane of the Stomach.*—1. Johann K——, twenty-seven years of age, complained for four years of a poor appetite, of a sensation and fulness after meals; suffers greatly from repeating; there is vomiting once in a while; bowels constipated.

October 31, 1890.—Status præsens: Patient pretty thin; chest normal; the stomach reaches to midway between the navel and the symphysis (tested by the gastrodiaphan and by the splashing sounds that can be produced); the stomach region is not sensitive on pressure.

November 2, 1891.—The examination of the stomach contents one and a half hour after the test-breakfast shows: HCl = 0; acidity = 34; rennet ferment +. Repeated examinations after the test-breakfast always gave about the same results, *i.e.*, the absence of free HCl.

Diagnosis: Gastritis glandularis chronica; atrophia mucosæ incipiens; dilatatio ventriculi.

The treatment consisted in direct gastro-faradization (October 31 to November 16, 1890, and April 13 to 26, 1891), besides the other usual therapeutic measures. The complaints of the patient soon ceased; his appetite improved and he had no repeating. As mentioned above, free hydrochloric acid could not be detected here after the test-breakfast.

On November 16, 1890, a trial was made to ascertain whether faradization would induce the stomach to secrete a sufficient quantity of HCl for its positive detection. With this end in view the patient was given while fasting 300 c.c. of water and was directly gastro-faradized for ten minutes; twenty-five minutes later a portion of the water was taken from the stomach; it looked greenish in color due to a small quantity of bile. The analysis showed: HCl +; acidity = 16.

In this way it was possible to prove that the faradic current in this particular patient, in whom otherwise free hydrochloric acid could not be found, produced a secretion of gastric juice with the presence of free hydrochloric acid.

The patient felt quite well during the whole winter after the treatment. On April 13th, however, the electrical treatment had to be resumed, on account of reappearing digestive troubles, but on April 26th the patient was dismissed as improved. The chemical condition of the stomach, however, has not visibly changed, in so far as there cannot be found even now free HCl one hour after the test breakfast.

2. March 14, 1891.—August S——, thirty-two years of age, complained for about three and a half years of obstinate constipation and pains in the gastric region, radiating to the spine and to the shoulders; has lost fifteen pounds during this sickness; there is no vomiting; appetite always fair; stomach largely distended; splashing sound down to a point two or three fingers' breadth below the navel; sleep good; during night the patient is no way troubled; tongue slightly coated.

March 15th.—Two hours after the test-breakfast nearly the whole quantity of the meal was obtained. The analysis showed: HCl = 0; acidity = 20; rennet ferment + (several other examinations showed again the absence of the free HCl after the test meals).

Diagnosis: Gastritis glandularis chronica with dilatation; beginning atrophy probable.

Besides HCl and a few washings of the stomach in the beginning, the direct gastro-faradization had been applied from March 15th to April 19th. The patient grew better, inasmuch as the pains ceased, but the examination of the stomach contents one hour and a half after the test breakfast showed, on April 17th, HCl = 0; acidity = 22; rennet ferment +. Thus there was no substantial change in the chemical condition of the stomach.

3. February 21, 1891.—Henry K——, thirty-three years of age, suffered for ten or fifteen years from "spitting of water." By this phrase the patient meant to express the belching of a considerable amount of a tasteless fluid from the stomach into the mouth, which he then expectorated every day or at least every other day. Sometimes this occurred ten or twelve times during the day. For the last eight or nine months the patient had this spitting after each meal. Appetite never good, although the patient could partake of each meal. When a boy he was strong and stout, but has been thin since his twentieth year. Sleep good; bowels moved every other day, but not regularly. During the last thirteen years there has been from time to time vomiting (*i.e.*, the ejection of the whole meal). Before the vomiting the patient had a sensation of oppression.

The physical examination of the chest organs reveals nothing abnormal. The stomach reaches down to within two fingers' width of the symphysis, as shown by gastrodiaphany and splashing sounds.

February 22d.—One hour after the test-breakfast: HCl = 0; acidity = 14; rennet ferment +. (Similar results have been obtained by examination on several other occasions.)

Diagnosis: Dilatatio ventriculi; gastritis glandularis chronica; regurgitatio; atrophia incipiens.

After direct gastro-faradization (from February 21st to March 26th every other day, and during April, 1891, once a week), and occasional lavage of the stomach, the patient's condition was ameliorated; "the spitting" greatly diminished (it now occurred only about once every other day), the appetite improved, and the patient felt stronger. Examinations of the stomach contents were made quite frequently; they always showed, however, nearly the same results; free hydrochloric acid was absent, but the ferments of the stomach, pepsin and rennet, were found to be present; the acidity was always very low, and varied from 14 to 22. Only once it was possible to detect the presence of free hydrochloric acid in traces; namely, on February 27, 1891, one hour after the test-breakfast, after ten minutes of direct gastro faradization the acidity was = 22.

At the end of the treatment the patient did not believe that he had gained in weight; the bowels moved regularly every day and the spitting had almost entirely ceased. This amelioration lasted even after the discontinuation of the treatment. I saw the patient again on November 3, 1891, and he reported that the "spitting" had not reappeared and that the bowels moved regularly every day.

Atrophy of the Mucous Membrane of the Stomach.—In the case of atrophy of the mucous membrane of the stomach, which had improved under lavage and a suitable mode of life, direct gastro-faradization was applied; this produced about the same result as the lavage of the stomach. The faradization in this case shows little that

is noteworthy, and I have given a full report of this case, which is very interesting from the clinical point of view, in the *New York Medicinische Presse*.[1]

Whereas in all above described cases (with the exception of Captain L. M——, Sub. IV.) after the frequent application of direct gastro-faradization there was a decrease, or rather a disappearance, of all the subjective symptoms of disease, in five others suffering chiefly from gastralgia there was noticeable a slight amelioration of the symptoms, but in no sense a disappearance of the same. In all these cases the galvanic current was afterward successfully applied.

A detailed description of all of them is given under the following heading of Galvanization.

B. **Direct Galvanization of the Stomach.**—The investigations made in regard to direct gastro galvanization are very few, for the reason that direct gastro-electrization has been until lately applied only rarely, and then usually the faradic current was administered. On direct gastro-galvanization there is in literature only one detailed contribution, by Bardet.[2] This author has treated one case of nervous vomiting and three cases of dilatation of the stomach, combined with symptoms of atony, with the constant current by means of a stomach electrode designed by himself.

In the case of nervous vomiting a remarkable amelioration ensued after three weeks of galvanization (the positive pole being in the stomach); the pains, however, remained just the same as before. In the three cases of dilatation the constant current was applied with frequent interruptions. In all these cases there was an improvement in stomach digestion, notwithstanding that the size of the stomach did not noticeably change.

As stated above, I have tried the application of the galvanic current in several cases in which faradization did not prove of much benefit, and have had good results. I refer to five cases of severe gastralgia from various causes (as will be seen from the histories); no therapeusis proved of any value, and even faradization was without effect, galvanization alone bringing benefit. I may be allowed to relate these cases in full, as they were reported in the *New York Medicinische Monatschrift* (September, 1891).

1. Augusta K——, twenty-two years of age, school-teacher, began treatment October 25, 1890. Patient complained for several months of having severe pains after meals; she has also become much weaker of late; from time to time there were attacks of pain of very intense character.

Examination showed the color of the lips and of the mucous membranes to be somewhat pale; at the apex of the heart there was a slight systolic murmur; the heart was not enlarged; pulse accelerated. Nothing abnormal could be detected in the lungs. The gastric region is sensitive on pressure, this being more noticeable at the epigastrium; the lower contour of the stomach is situated somewhat (one finger) above the umbilical line. The urine contains neither albumin nor sugar.

Examination of the stomach contents on October 26, 1890, two hours after the test-breakfast, showed: HCl + ; acidity = 34.

Diagnosis: Insufficientia mitralis; gastralgia nervosa. The patient was gastro-faradized internally from January 1 to January 10, 1891, but without any special result. Codeine and phenacetin, which were given to combat the pains, were without effect.

January 23, 1891. Direct galvanization of the stomach (negative pole in the stomach, strength of the current being 15 to 20 milliampères) was administered every third day up to February 4th; thereafter once a week up to March 4th, on which day the cure was considered as finished.

After the first galvanic sitting the patient reported that the pains became slighter and the attacks less frequent. On February 4th the patient said that she had been free from pains since the last galvanization. She gained in weight thereafter, and has had no pains thus far up to date.

2. The history of patient, H. F——, thirty-five years of age, clergyman, has already been partially reported by me. Three years ago I presented this patient at the German Medical Society of New York as a typical case of gastrosuccorrhœa continua chronica, and published the same in the *New York Medicinische Presse*, September, 1888. The patient at that time had been sick for four years. In reference to the condition of his disease I said at that time, that, notwithstanding the constant vomiting had been successfully stopped, and the patient had been brought into a much better condition by the rational treatment (lavage of the stomach, alkalies, and suitable diet), the sickness as such, the continuous flow of gastric juice, however, had not been relieved.

In the above paper I said: "Objectively I have been able to note a diminution of the quantity of fluid found in the stomach when fasting; but I have not succeeded in reducing the excessive secretion of the stomach to the normal." From September, 1888, to December, 1890, the condition of the patient, who was all the time under my observation, remained the same; there was always found in the stomach when fasting a certain amount (40 to 80 c.c.) of gastric juice containing hydrochloric acid and the specific ferments of the stomach (pepsin and rennet). During all this time the patient was never free from pains, although they were not of an intense character. In the year 1890 the pains began to increase; they were principally in the epigastric region and radiated to the back. On account of his pains the patient could not lie on his left side, and complained of a very restless sleep. The cough, which appeared in the middle of 1889, then became more intense and frequent, although nothing could be detected abnormal in the lungs. Palpation of the gastric region caused pain. Chloral hydrate produced but little influence on the pains, and bromide of sodium, which the patient took for quite a while, had diminished the cough but not the intensity of the pains.

During November and December, 1890, direct gastro-faradization was applied, but this, likewise, did not have the desired effect. For this reason, in the beginning of January, 1891, direct galvanization of the stomach was administered first twice a week and thereafter only once a week. At the end of February last the galvanic treatment was discontinued. Immediately after the first galvanic séance the pains became much slighter than ever before; after a few more sittings the intense pains the patient used to complain of before ceased entirely. In March last it was noticed that the stomach of the patient was empty when fasting, something that had never before happened during the three years of treatment. Since that time the patient has often been examined when fasting, and there was always the same result found, namely, the stomach was empty. Thus far the pains have not reappeared, and the patient is better and healthier in appearance, and has gained several pounds in weight. Thus the previous condition of continuous flow of gastric juice has not existed since March last, and it is interesting to ascertain the chemical condition of the stomach at present. An examination of the stomach contents, made for this purpose, in May, 1891, one hour after the test-breakfast, proved the presence of hydrochloric acid and an increased acidity (= 120).

In this way we see that the previously found hyperacidity persisted, although the abnormal secretion of gastric juice during the time that there is no food in the stomach has disappeared. Whether this favorable turn has been brought on by direct galvanization is hard to tell, although there are no other apparent circumstances by which the sudden change in the condition of the stomach secretion could be explained, except the direct galvanization.

On account of the persistent cough the patient was

[1] September, 1888.
[2] Bardet: Bull. Gén. de Thérap., 1884, t. 106, p. 529.

sent to Dr. W. Freudenthal, of this city, who found a lingual tonsil and an elongated uvula. The patient was treated accordingly, and although the cough did not disappear entirely, it is now much easier.

I may be allowed to remark that this is, according to my knowledge, the first case of gastrosuccorrhœa continua chronica mentioned in literature which was cured with cessation of that anomalous action.

3. Charles J——, aged twenty-one, merchant, complains for three months of having pain immediately after eating, by reason of which he is prevented from partaking of a sufficient quantity of food; there was vomiting once in a while; bowels constipated. Patient has become thinner and feels weak; he coughs from time to time, and is uneasy about his lungs.

July 9, 1891.—Physical examination shows thoracic organs normal; sensitiveness on pressure over the region of the stomach; no enlargement of the stomach can be discovered; the urine is free from sugar and albumin. On account of the weakness of the patient, pills of iron and strychnine were given at first.

July 10. the stomach contents were examined one hour after the test-breakfast by means of the stomach-bucket: HCl +; ten times diluted +; fourteen times diluted = 0. The chemical function of the stomach is not markedly disturbed; the acidity being only little above the normal limits.

Diagnosis: Gastralgia of nervous origin in combination with anæmia.

The patient was gastro-faradized internally every other day for a week, but without any apparent result; he still complains of being unable to partake even of a small meal; besides, he has often acid eructations. In addition to the pills the patient was advised to take, if necessary, three times a day, half a teaspoonful of a powder, consisting of sodii bicarb., elæosacch. menth. pip., āā equal parts. This powder gives the patient some relief, although his condition, as such, has not altered. He went to Washington on a business trip, and returned after a week, complaining of his previous troubles, besides of being restless and excited and sleeping poorly.

July 24th.—Sodium bromide was given, and direct faradization of the stomach was resumed, electricity being applied on July 24th and 27th. He, however, noticed but little amelioration, and was unable to eat sufficiently.

As the faradic current did not seem to achieve much in this case, direct gastro-galvanization was resorted to on July 29th. The negative pole was introduced into the stomach, the other (positive) electrode was placed beneath the ensiform process, a little to the left, for five minutes, thereafter for three minutes on the left side of the spine, over the sixth dorsal vertebra, and then again for two minutes in front. The strength of the current was 20 milliampères.

On August 1st the patient reported that he felt much better after the galvanization, and, what could be noticed most markedly, he could eat well, without having pains afterward; he was galvanized once more in the same way. The pills were discontinued. The patient subsequently caught cold and suffered from a pharyngitis, and in order to avoid an irritation of the throat the galvanization was omitted until August 8th, on which day the throat appeared well again. On August 8th and 10th gastro-galvanization as described above Meanwhile the condition of the patient was highly ameliorated; he ate, to use his own expression, "like any other man," and had no pains whatever. He had a much better appearance, the cure was considered as finished, and the patient went to the mountains for his vacation.

In November last he reported that he had been all right since the electrical treatment.

4. June 15, 1891.—Miss Ida S——, twenty-seven years of age, began to have pains in the gastric region, especially after meals, six years ago. There was vomiting from time to time, and loss of appetite. The condition of the patient was somewhat improved after a sea-voyage to Germany. While there, however, the condition grew worse in 1887; vomiting of blood came on, and the patient was treated for ulcer at Frankfort-on-the Main. She felt somewhat better and returned to New York in 1889. While at sea she got worse and had several spells of vomiting of blood. Since that time the patient has suffered all the time, with only short intermissions, from entire loss of appetite, pains directly after each meal, and very frequent vomiting. The attacks of pain were often unbearable and the patient was frequently obliged to take refuge in morphine and alcoholic drinks, although even this means did not give her much relief. She is emaciated to a high degree.

Status præsens: Pain on pressure in the epigastric region; the stomach is deeply situated, from one to two fingers' breadth below the navel; there is splashing; the right kidney is movable.

June 26, 1891.—One hour after the test-breakfast: HCl +; acidity = 24.

Diagnosis: Enteroptosis; gastritis glandularis chronica; cicatrized ulcer; gastralgia.

Treatment: Tr. nuc. vomic., aq. amygdal. am., āā equal parts. M. S.: Fifteen drops, t. i. d., twenty minutes before meals. Sodii bromidi, 8.0; aq. menth. pip., 60.0. M. S.: A teaspoonful morning and evening.

[Tr. ferr. aromat. (Pizzala), two teaspoonfuls three times a day, had to be discontinued, as this preparation did not seem to agree with the patient.]

From June 16th to July 8th, direct gastro-faradization was applied every other day. On July 6th the patient began to take acid. mur. dil., twelve drops t. i. d.

Although direct faradization of the stomach had decreased the severe attacks of pain, they nevertheless persisted, and there was still the highest degree of anorexia. The patient could force herself to partake of only the smallest amount of nourishment, and even then vomiting ensued once in a while. On July 8th she again had a very severe attack of pain, and as the remedies given (bismuth and phenacetin, āā 0.4; codeine, 0.01, t. i. d.) did not bring much relief, on July 10th direct galvanization of the stomach was resorted to. From July 24th the galvanization was applied regularly every other day.

After the first electrical sitting the patient could eat more, the vomiting stopped, and the pains soon ceased entirely. One week after the galvanic treatment the patient had a better appearance and reported that her appetite was good and that the food agreed with her quite well; the previous nauseous feeling and the pains were absent.

July 24th, the patient was sent to the mountains. On August 24th she reported that she had gained four and a half pounds. The severe attacks of pain did not reappear during all this time, although the patient has still a feeling of uneasiness after meals lasting for about an hour; she is obliged to keep quiet during this time, and the process of digestion can proceed fairly; there is no vomiting.

Examination of the stomach contents on August 26th, one hour after the test-breakfast shows: HCl + (traces); acidity = 30; rennet ferment +.

The galvanization was continued once a week during October and the first part of November, and then stopped. The patient meanwhile had gained several pounds and felt very well; she fully enjoys her meals and has no pain.

5. Th. G. H——, thirty-seven years of age, engineer, was always well until eight years ago, at which time he had to undergo an operation for an anal fistula and was etherized. A few days after this operation the patient began to have pain in the scorbiculum soon after meals. The appetite was good. The heart-action was irregular, and he became ill-humored. Three years ago his condition improved; but in April, 1891, a deterioration ensued after he had been to a festival. There was oppres-

sion, especially after meals; very frequent eructations (after which the patient felt better), the bowels were irregular; heart-action irregular from time to time. Appetite good. The main complaint of the patient refers to intense pains appearing in the gastric region, usually after meals, but sometimes, at irregular times, there is also frequently an apparent cessation of the heart-beat and in connection with it a sensation of extreme fear.

Status præsens: At the right manubrium sterni a systolic murmur is audible; the pulse is intermittent at long intervals. Stomach dilated; splashing is heard down to a point one finger's breadth below the navel. The gastric and epigastric regions are sensitive to pressure.

July 22, 1891.—One hour after the test-breakfast examination by means of the tube (only a small amount of material was removed and it was tinged with blood): HCl +; acidity = 4.

Diagnosis: Dilatatio ventriculi with erosions (perhaps ulcer); intense anæmia; it is a question whether the murmur is caused by the anæmic condition or by aortic stenosis; gastralgia.

Treatment: Pizzala, gymnastics, rowing, bathing; direct gastro-faradization every other day from July 23d to July 31st. The patient felt better; the pains were easier and the intermission of the heart-beat appeared less frequently. Notwithstanding this there was still always a sensation of oppression after meals, and from time to time the old attacks of pain returned, although less frequently than before.

The stomach was examined again on July 31st, one hour after the test-breakfast. On account of the erosions present the tube was avoided, and the contents obtained with the stomach-bucket: HCl +; dilution twelve times +. The acidity was therefore somewhat increased, and the following powder was administered: Magnes. ust., 5.0; bismuth subnitr., 10.0; sodii carbon. et bicarbon., sacch. lact., āā 15.0. Half a teaspoonful three times a day, two hours after meals.

Instead of faradization, direct galvanization of the stomach was applied every other day from August 2d, to 14th. The patient reported on August 4th that the pains had considerably decreased and that there was less oppression after meals; after the first week of galvanization the pains entirely disappeared. The intermission of the heart beat was not noticed, and on auscultation, I was not able to distinguish the murmur previously present at the manubrium sterni. The epigastric region was but little sensitive to pressure and in no way painful.

August 14th, the patient said that he had never felt as well during the three years of his sickness as during the last few days.

An examination of the stomach contents one hour after the test-breakfast, by means of the stomach-bucket, on August 14th, showed HCl +; five times diluted + little; eight times diluted = 0. Thus the acidity was somewhat diminished.

The patient was dismissed from treatment as considerably ameliorated, and sent to the seashore for further recreation. and recuperation. He returned to the city in October, having gained eight pounds in weight, and now has no complaints.

Although the five above-described cases are quite different from each other as regards the type of disease, they all, however, have one point in common, namely, a severe gastralgia, which resists every kind of treatment; the gastralgia, however, is the symptom which chiefly troubles the patient, and, as time goes on. seriously endangers his subjective and objective welfare. In all these cases the constant current, applied to the stomach-walls, brought much benefit, and this in quite a short time; the gastralgia succumbed to the influence of galvanization. This was the reason why in the two following cases of severe gastralgia I applied direct gastro-galvanization at once, without having first tried the faradic current.

6. Dr. L. R—— came under treatment October 14, 1890, complaining of attacks of pain after eating, which had existed for some days. Patient examined: chest normal, stomach not dilated, the epigastric region sensitive to pressure. On October 15th, the contents of the stomach were examined by means of the stomach-tube, one hour after having taken the test-breakfast: Reaction acid; HCl = 0; Rennet +.

As regards diagnosis, an ulcer was not believed to be present, but the trouble considered to be one of nervous character, as a result of mental overwork. Patient was given HCl, and on the 16th was faradized; on the 18th he stated that he obtained no relief from the faradization. From this date I did not see the patient again until January 29, 1891; he stated that at first he felt pretty well, but since the end of December had felt very bad; every day he would have two or three attacks of very severe pain, beginning in the scorbiculum and extending from there to the back. He was able to cut short an attack occasionally by taking food. He had been taking powders of bismuth, codeine, and belladonna, without obtaining any relief. He was somewhat emaciated as a result of the pains and the small amount of food taken.

An examination of the contents of the stomach showed a slight hyperacidity—with this exception the examination gave the same results as on October 14, 1890.

The diagnosis of gastralgia, made on October 14, 1890, was substantiated by the fact of the alternating character of the acidity. [February 25, 1891, one hour after the test-breakfast: HCl +; acidity = 96]

We advised the patient to have direct galvanization of the stomach applied. The gentleman did not place much confidence in electricity (especially since direct faradization had benefited him but little), but was persuaded to submit to the treatment. From February 5th to the 13th he received the constant current every other day; then every third day until the 28th; during the month of March it was only applied once a week, and after that it was omitted entirely.

The method of applying the current was the same as in the preceding case—negative pole in the stomach; strength of current, 15 to 20 milliampères; duration, ten minutes.

The progress of the case was as follows: After the first galvanization the patient stated that his pains continued, but were not as severe; after the second and third the number of attacks was diminished and the amount of pain was less severe; after the fifth application the pains had almost entirely disappeared; in the latter part of February they returned only once or twice, and were not at all severe. After this they did not return. The patient could eat well, his appearance was better, and he considered himself perfectly well. I deemed it advisable to apply galvanism once a week throughout the month of March, although the patient no longer complained of pains. He has enjoyed perfect health since then and has remained free from the attacks of gastralgia. Dr. L. R—— returned on December 1st and stated that for the past three weeks he had had exacerbations of pain, similar to those of a year ago, though less severe. Galvanism was begun at once and the probability that the duration of the affection will be shortened is shown by the fact that the symptoms have been already somewhat relieved.

My reason for selecting the negative pole for introduction into the stomach is that the cathode is understood to produce a stimulating action. In the majority of the cases treated by me I presupposed a diminished function, either of the secretory nerves or of the nerves which control the carrying along of the contents. Furthermore, the positive pole relieves pain, and so this was placed on that part of the skin where the pains were most severe.

7. August 10, 1891.—Gustav L——, aged twenty-six; always felt well until September, 1890, when he suddenly became sick, with loss of appetite, diarrhœa, and cramps; for five days he was not able to eat hardly anything; in about three or four weeks he was better, in so far that he

could eat. Until January, 1891, the patient felt well, then he began to suffer from eructations, especially in the morning, poor appetite and pains in the gastric region. The pain began in the scorbiculum and radiated to the back. The condition has remained the same up to date. After meals the pain was not increased, except when the patient had partaken of a large amount of food. The patient lost considerably in weight and was quite weak.

August 10, 1891.—Status præsens: Thoracic organs normal; epigastric region sensitive to pressure; the lower contour of the stomach is supposed to be situated in the umbilical line, as splashing can be produced down to this limit.

Diagnosis: Dilatatio ventriculi; gastralgia; ulcus(?).

August 22d.—The contents of the stomach were obtained one hour after the test-breakfast, on account of the doubtful ulcer, by means of the bucket: HCl +; five times diluted + (traces).

The patient was gastro-galvanized internally every other day from August 15th to 23d, thence to the end of September twice a week, and thereafter once a week until October 19th.

September 9th.—The patient reported that he had not had any pains since September 5th. The appetite was good and he felt generally much better than a fortnight ago. During the remaining time of treatment the patient had almost no pains whatever and gained three pounds in weight.

To my cases of severe gastralgia treated by direct gastro faradization the following case, treated by Dr. Alfred Meyer, of this city, may be added.

Dr. Alfred Meyer was kind enough to send me a full report of his case and I may be allowed to publish the same with Dr. Meyer's own words. He wrote to me as follows:

"I saw the patient for the first time on September 11, 1891. He was twenty-eight years of age, intelligent, of rather a nervous type and light build. His sickness had begun about seven years before, rather suddenly, after taking a glass of ice-water while overheated. His complaint consisted of periodic attacks of intense pain in the epigastrium, accompanied or unaccompanied by vomiting. Originally there had been long intervals of good health between the attacks, but these intervals of comfort had grown shorter and the duration of the attacks longer. Present attack had begun in January of the present year. Patient had taken to bed in May, where he had been almost continuously, up to the time of my seeing him. During these years the treatment had included a very large proportion of the remedies usually administered in gastric diseases, whether of a functional or of an organic nature. They had been given singly and combined, allopathically and homœopathically. They included: Bismuth, bicarbonate of soda, pepsine, lactopeptine, muriatic acid, iron, iodoform, nitrate of silver, arsenic, belladonna, morphine, codeine, creasote, hypophosphites, nux vomica, tannin, charcoal. In addition, various forms of counter-irritation, external galvanization, rectal alimentation, and, some years ago, a few washings by siphonage. The patient describes the pains as radiating into the right and left hypochondrium, and into the back between the shoulder-blades. The pain was either lancinating or boring or grinding, and accompanied frequently by a feeling as though somebody were playing the piano on the patient's stomach. There seemed to be no relationship between the pain and the introduction of food into the stomach; in fact, there would frequently be distinct relief after eating or drinking. The vomiting had usually been of large quantities, according to the patient's statement, had never contained blood, but often remnants of food taken as much as twelve hours before the vomiting.

"Physical examination showed heart and lungs normal, liver and spleen normal, tongue heavily coated, slight sensitiveness to pressure in the epigastrium, slight gleety discharge from the urethra. Light percussion seemed to indicate the existence of a moderate gastrectasia. Under the supposition that there was a stenosed pylorus from an old ulcer at that site, with secondary dilatation, feeding by the mouth was stopped, and the patient was placed, beginning September 12th, upon deep rectal alimentation with peptonized milk, a mixture of meat pulp and sweetbread, and afterward of milk and whiskey. This was kept up for five days, during which time nothing was allowed to pass the patient's mouth except a few tablespoonfuls daily of an infusion of cundurango. There was a daily recurrence of pain, commencing usually after 1 P.M., gradually increasing in violence, and toward evening the patient would be found grinding his teeth and tossing restlessly from pain. He received daily an injection of morphine and atropine.

"On September 17th gradually increasing quantities of milk with lime-water or barley, by the mouth, were commenced, combined with rectal alimentation; later Mellin's food, sweetbread, and wine-jelly, and finally rectal alimentation was entirely withdrawn. The morphine injections were kept up in diminishing doses until October 3d. During a portion of this period the patient received varying quantities of tinct. belladonnæ, without marked benefit, though the amount taken was at no time sufficient to produce distinct physiological effects. A solution of bromide of soda was also tried, because of a growing conviction that the patient was suffering primarily from a neurosis of the stomach. On September 24th, the patient was given a test-meal of a French roll and a cup of tea without milk. On this occasion he was seen in consultation by Dr. Einhorn. The expressed stomach contents were found to contain an abundance of free HCl, an acidity of 160, being nearly three times the normal. On September 26th, galvanization with Einhorn's deglutable stomach electrode was commenced, strength of the current 14 milliampères. Daily sittings after that until October 26th; duration from fifteen to twenty minutes, strength from 13 to 29 milliampères. After the first week of galvanic treatment the injection of morphine was stopped entirely, the patient being nearly free from pain. Some of the credit for this result may possibly be due to a solution of cocaine and belladonna employed at the same time, but it is only fair to say that there was a continuance of the favorable condition under galvanization alone, the use of the anodyne mixture having been practically suspended. October 8th, 10th, and 12th, small hypodermics were again required. In view of this recurrence, a solution of atropine was ordered, and continued until October 21st. After October 26th galvanization was employed on alternate days only, namely, October 27th, 29th, and 31st, the patient feeling sufficiently convalescent to permit his walking to the sofa, and spending a few hours there, daily. The interval was then prolonged, no current being applied November 1st, 2d, and 3d. On the third, he began to have 'crampy' pains again, which culminated in an attack of vomiting at 7 P.M., and again at 1.35 A.M., November 4th, this time amounting to a pint and a half of mainly fluid material. In view of this episode of pain and vomiting (the latter being the first he had had since he had been under my observation), I determined to resume the treatment by galvanization, and the patient had sittings on the 4th, 5th, 6th, 7th, 8th, and 9th, which concluded this method of treatment, for the patient had attacks of vomiting November 9th—1 A.M., half pint; 3 A.M., one pint and a quarter; 8 A.M., one quart; 3 30 P.M., one pint and three-fourths, and required a morphine injection on the evening of the 9th. On the morning of November 10th daily lavage of the stomach was commenced, and on this occasion some bits of prunes were found in the wash-water that must have been in the stomach nearly forty-eight hours. On this date the patient received his last hypodermic. In addition to the daily lavage, he has been receiving Fowler's solution, and a solution of bromide of soda and chloral t.i.d. He is on a very liberal diet, is up the entire day, feeling well and anxious to go out and resume his ordinary routine.

"With reference to the employment of internal galvanization in this case, though it did not prove curative, it was, in my judgment, distinctly beneficial, in spite of the scepticism of the patient, who had had external galvanization without any improvement, before I had seen him, and was therefore rather averse to its application by this modified method. The introduction of the electrode into the stomach and its removal were always accomplished by the patient himself without the slightest difficulty or annoyance."

In reference to the therapeutic results of direct electrization of the stomach I might be allowed to give the following *résumé*:

Direct gastro-faradization proves to be useful in many ways in most chronic diseases of the stomach. The favorable results appear very clearly and pretty quickly in those cases of stomach dilatation which are not caused by any obstruction of the pylorus, but merely by the relaxation of the muscular coat of the stomach. Here the gastro-faradization is beneficial, no matter whether in these cases there is hyperacidity or subacidity of the stomach contents. Cases of relaxation of the cardia (eructations) and also of relaxation of the pylorus (presence of bile-secretion in the stomach) were very favorably influenced by faradization. Here the result was most markedly pronounced, inasmuch as, besides the subjective amelioration of the patient, the objective examination showed at the same time the absence of bile in the stomach-contents (there was, however, only one case of relaxation of the pylorus under observation).

Direct gastro-galvanization was administered with very good results in cases of obstinate gastralgia; several of them had resisted every therapeutic means, but yielded to the influence of galvanization.

REPORT ON WOUNDS BY MANNLICHER BULLETS.

By E. R. STITT, M.D.,

ASSISTANT SURGEON UNITED STATES NAVY.

The first opportunity for studying the effects produced by the projectile adopted within the last few years by the leading European nations, was in the recent Chilian civil war, after the battles of Concon and Placilla. About one half the Constitutional army were armed with the modern weapon of the type adopted by Austria, and popularly known as the "Mannlicher;" the remainder carried arms similar to those used in our army, which was also true of the supporters of Balmaceda. This explains why such a small proportion of the wounds was caused by the steel bullet.

For the benefit of those who have not made military surgery a special study, a description of the modern projectile is here given: The weight of the bullet is 243 grains, length 1.2 inch, diameter, 0.322 inch; it consists of a core of lead, hardened with five per cent. of antimony, encased in an envelope of steel 0.131 inch thick.

In Italy a projectile of smaller calibre and having a capsule of copper is used; the English bullet is very similar, but with a steel exterior; in fact almost every country, with the exception of our own, has changed its system of small-arms, adopting a rifle of small calibre.

Another weapon which we shall briefly consider, is that of France, the Lebel; in this the projectile is practically similar in size and shape to the Mannlicher, but is made up of hardened lead coated with nickel; it has not the thick resisting exterior possessed by the latter, and this probably explains the differences in the lesions produced.

The French Academy of Medicine made a series of experiments on twenty corpses, using the weapon and projectile adopted by that country; firing at the bodies at varying distances, and under different conditions. As a result of these trials it was reported: 1. That owing to the smallness of the apertures, the cure of the wounds would have been very difficult. 2. That at less than three hundred yards, the lesions were similar to those caused by the 43 calibre Gras bullet, except as regarded fractures, these occurring only when impact was tangential; otherwise the bone was simply pierced. 3. That the lead escaped in small points from the capsule, and these remaining in the wound, would complicate treatment.

Now, let us see to what extent these facts agree with those noted after observing the wounds produced in actual conflict, and whether their care and cure accord with the theories induced from the phenomena noted.

The cases observed in the Chilian hospitals divide themselves naturally into two classes: flesh wounds, and wounds complicated by bone lesions. As regards the first class, the wound of entrance is made smaller than the one caused by the lead bullet of greater calibre; it is perfectly round, without the slightest laceration of the margin; in some cases, owing to the thick layer of dirt with which many of the wounded were covered, it was almost impossible to locate it; in the wound of exit, the small size, as compared with that produced by ordinary projectile, is more noticeable; it is but slightly larger than the wound of entrance, also round, and with non-lacerated border (in three or four cases this did not pertain, fragments of bone having been forced through the opening). This is due to the fact that the projectile never loses its shape or splits up into two or more pieces on striking bone or some other hard substance. There was but one case reported where the capsule was stripped from the lead core, and this was supposed to have been caused by its striking a rifle before entering the body; invariably, when a bullet was cut out its former shape was unaltered. Owing to its smooth surface and consequent great mobility, the ball is easily found under the skin or fascia; yet, on cutting down upon it we find the object of our search to have disappeared; the method adopted to remove it was, after locating, to make an incision, cause the bullet to present at the opening, and seize it carefully with the forceps.

What a great difference when a lead bullet strikes a substance; then axial rotation is lost, and it plunges through the tissues, increasing size of track, as well as wound of exit; this never occurs with the steel bullet.

Authorities have taught that devitalization of tissue was proportionate to the velocity of the projectile, and that this was the reason for the slower healing of the wound entrance. That further inquiries as to the cause are necessary, is shown by the fact that in steel bullet wounds, although the condition of greater primary velocity exists, yet never is there appreciable difference between the time of healing of the wound of entrance and that of exit.

It seems more probable that the septic condition of the proximal portion of the channel made by the ball is the explanation. As bearing on this, we would note that foreign substances are most rarely introduced into the wound by the bullet under consideration, while with the other this is the case almost invariably; and it is certainly reasonable to suppose that the greater portion of the septic material would be deposited at or near the point of entrance. Non-introduction of foreign material is claimed for the steel-coated bullet, on account of the aseptic condition of the wounds, almost always healing by first intention where germs were not introduced by means of the probe; the probing of a simple flesh wound indicates morbid curiosity.

The most noticeable advantages the smaller projectile presents from a surgical standpoint, are in the wounds of the lung; in one case where the ball passed through the right lung, no other symptom was recorded than a slight hæmoptysis following the reception of the injury; careful auscultation twice daily failed to elicit the slightest inflammatory process, no elevation of temperature; the wound healed, and in a few days the patient was discharged from hospital. In several similar cases, some complicated by fracture, it was observed that even when inflammation

ensued it was limited, and probably secondary to pleurisy caused by the wound—a costal fracture.

It was the consensus of opinion that the untoward results attending abdominal wounds were practically identical, whether caused by lead or steel ball; it would appear, however, from the maintenance of axial rotation, the absence of change of form, and the aseptic condition of the track traversed, that the prognosis would be more favorable when the wound was produced by the latter.

Just as in wounds of other tissues, the results following the passage of a steel projectile, as compared with those produced by a lead one, differ more or less, according to the part of the body struck. So it is with lesions of bone; when it is a short or a flat bone the injury is much less serious; in the case of a long bone, however, the damage inflicted is practically the same, except when the ball passes through without fracturing.

With the exception of lung wounds, those of the short and flat bones best exhibit the humane attributes of the modern rifle. In several cases where the ball passed through the bones of the face, only slight deformity resulted; similar results were noted when the bones of the hand were involved; never more than one metacarpal bone fractured, and only slight laceration of overlying tendons; the wounds healing in one-half of the time required ordinarily; invariably motion was perfect after recovery. In the flat bones there was rarely any comminution; in the short ones, although present, it was slight, never presenting the appearance of having been struck by a hammer, as is frequently seen when a lead ball is the cause of the injury.

With long bones, unless the projectile simply passes through without fracturing, the immediate result differs but slightly from that produced by a lead bullet, and, strange to say, the length of bone comminuted is as a rule greater; the fragments, however, are less in number and larger in size; the probable cause for this is the wedge-like action of the steel ball; in a case observed, when resection of the humerus was necessitated on account of an extensive comminuted fracture, two fragments were removed which when put together showed a perfectly round opening, having the appearance of having been drilled; from this it would appear that in cases where the bullet does not pass entirely through, it first drills a hole, then loses in velocity; and as its momentum varies as square of velocity, so that is greatly reduced and a fracture is caused, the fracture being longitudinal rather than transverse in character.

Nothing so conclusively proves the superiority of the steel bullet as the fact that, on November 15th, all those wounded by the Mannlicher projectile had been sent out from the wards of St. Augustine Hospital (there were originally more than 2 000 cases in this institution), while there remained at least 300 of those wounded by rifles using lead bullets of .40 calibre or more.

Before concluding, it would be interesting to make mention of a singular coincidence, noted at the San Juan de Dios Hospital; here the cases had been admitted to wards without regard to any system of classification, yet on first visiting the wounded, two cases of gunshot wound of the elbow-joint were seen, lying in adjacent beds; one caused by a lead, the other by a steel bullet; the former produced such great disorganization of the joint that amputation was necessary, while in the latter case, although the course of the ball was identical, nothing more serious resulted than a moderate synovitis; rest and passive motion restoring function in a few days.

Chirography and Merit.—It is related of the late Sir Richard Quain, whose handwriting was execrable, that when a student he once went up for an examination, in which he confidently expected to take the prize. However, the medal was given to somebody else, and on inquiry it was found that his writing was so bad that the examiner had been able to read only one of the answers.

PERICHONDRITIS AURICULÆ AFFECTING BOTH EARS.

By THOMAS R. POOLEY, M.D.,

SURGEON-IN-CHIEF OF THE NEW AMSTERDAM EYE AND EAR HOSPITAL; PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

In the "Transactions of the Medical Society of the State of New York for 1881," and in the MEDICAL RECORD of March 19, 1881, I have reported a case of acute inflammation of the perichondrium of the auricle in which reference is made to the rarity of the disease, and the principal features which characterize it are set forth. I am now enabled to add another observation of this rare form of disease of the ear, in which both ears were almost simultaneously affected, and ran a parallel course. This is, so far as I have been able to ascertain, the only case in which the disease was bilateral that has been observed. The accompanying photographs were taken

Right Ear.

when the disease was about at its height in both ears, and show the appearances of the ears at that time. It is to be regretted that I did not have an opportunity to get another, showing their condition at the termination of the case.

Inasmuch as I gave at the time of publishing my last case a minute detail of the clinical symptoms and de-

Left Ear.

scription of the appearance of the ears, I shall now content myself with as brief an account of this one as possible, the chief interest of which lies in the symmetrical development in both auricles.

Mary G——, aged twenty-two, came under my care, July 30, 1891, suffering from otitis externa furunculosa of both ears. She was very poorly nourished, owing largely to the fact that her teeth were so defective that she could hardly masticate, and lived largely on slops. She was also anæmic to the last degree, and suffered from irregular and painful menstruation.

For a period of four weeks she attended my office for treatment, during which time she suffered greatly from diffuse swelling of the auditory canal and constantly recurring furunculi, which were opened and always gave issue to a bad-smelling, thin, watery pus. All the known local methods and the use of constitutional remedies, including the much-vaunted calcium sulphide, were of no avail in arresting the disease. I accordingly proposed to her to enter the hospital for a time, which she did on August 28th. At this time the meatus of the left ear was almost completely closed by swelling and furunculi. The right was in the same condition to a less degree, pain was severe in character, and she was worn out with suffering. There was considerable discharge from the canal of both ears from the incisions which had been made. Constant applications of heat were made by the use of spongiopilin wrung out of hot water, large doses of iron and quinine, generous diet of a fluid kind, and stimulants were given. There was a temporary relief of her suffering, but no diminution in the swelling; but, on the contrary, the concha of the left ear became much swollen and bulged outward, effacing its natural depression. The same extension of the inflammation to the concha began a day or two later in the right ear, and from this time on followed about the same course in both ears, except that throughout it was more severe in the left, but both showed the typical features of perichondritis. The swelling of the canal diminished, but from the concha the swelling successively invaded by slow extension the entire anterior surface of the auricle except the lobule, involving in turn the concha, helix, anti-helix, and the fossa helicis, in short, all the anterior surface except the lobule. The appearance of the ears at this time are accurately shown in the cuts. The character of the swelling was uneven—in some places diffuse, in others nodular. When it had reached its height on the anterior surface of the auricle, and had reached the helix, it began to encroach upon the posterior surface of the auricle, every part of which, except the lobule, in due time became affected. The swelling was of a dark red color, and boggy to the feel. There was an ill-defined sense of fluctuation, most marked on the posterior part of the auricle just above the lobule. At this point, which marked the maximum swelling in both ears, an incision was made, and these were the only ones made during the treatment except in the ear canals, giving vent to a small quantity of thin, glairy-looking matter, mixed with yellowish-white shreds; no blood escaped. A probe could be passed from this opening either along the anterior or posterior surface of the auricles to the helix. The cartilage was roughened, hard, and its perichondrium, which was readily detached, raised, together with the skin, on the probe.

September 10th.—Measurements of both ears were made as follows: Right ear, from superior border of helix to inferior border of lobule, 5 ctm.; from posterior border of helix to anterior border of tragus, 2.8 ctm. Left ear, in same dimensions, respectively, 5.6 ctm. and 3.1 ctm. The treatment consisted in the injection, once a day, through the openings made by the incisions, of solutions of bichloride and carbolic acid, and the almost constant use of heat and pressure. The appearance of the swelling, as it appeared in different parts of the ear, and the sense of fluctuation, tempted one to make incisions, but this was never done except at the sites referred to.

October 12th.—When last seen the inflammatory character of the disease had entirely subsided, the pain all gone, the general condition of the patient much improved, and only the usual deformity remained. This condition was almost exactly the same as is shown in Fig. 2 of my previous article (loc. cit.).

This case, like the others which I have seen, was of idiopathic origin; there was no history of trauma, and the occurrence of the disease on both sides at the same time would speak for its constitutional origin, and argue for its being due to some specific morbid process or germ, as would also the great amount of pain and constitutional disturbance. It seems to me that the same conditions which favor and produce an inflammation of the external auditory canal, if they be long continued, finally result in perichondritis, since all the cases I have yet observed, and those hitherto observed, begin as an external otitis.

In referring to the treatment in my former article I say: "It now seems to me to have been a mistake to have made so many incisions as I did. They were followed by no relief to the pain, nor did they in any way hasten the cure. It may be well to make an incision into the most dependent part of the swelling to gain access to the cavity. For the rest the cavity should be drained by a drainage-tube, and injected with some antiseptic solution, such as carbolic acid, and systematic pressure employed." Acting upon the experience obtained in this case, I only made an incision to gain access to the cavity, nor did I use a drainage-tube, which I should now consider as painful and unnecessary, as the opening made by the incision does not show any tendency to close if the wound be injected daily. The disease is, in my judgment, a self-limited one, which once begun will continue until every part of the cartilaginous structure of the ear is involved, and the simple plan of treatment, expectant in character, which is here recommended, is all that is indicated. Constitutional remedies, with tonics, and narcotics to relieve the pain, which is especially severe at night, are very useful. That a more energetic plan of treatment than I have recommended may diminish the degree of resultant deformity is not within the line of my experience and observation.

Progress of Medical Science.

Antiseptic Treatment of Ptyriasis Versicolor.—The pathogenic rôle of the *microsporon furfur* is secondary, the parasite developing only on the skin of dyspeptics affected with seborrhœa. Hence, there are two indications in the rational treatment of this affection.

General and Antidyspeptic Treatment.—1. Encourage intestinal evacuations by purgatives, salicylate of magnesia, castor-oil. 2. Associate intestinal antiseptics with these purgatives and with alkalies.

℞. Bicarbonate of soda,
Salol,
Magnesia..... ....āā 5 grammes.
Divide into fifteen powders and give one before each meal.

Local Antiseborrhœic and Parasiticide Treatment.—1. Each morning hot lotions and frictions with green soap, allowing the foam to dry on, and subsequent cleansing bath with plenty of water. 2. Every second day, sulphur baths followed by frictions with green soap, with the addition of naphthol or pumice-stone.

℞. Green soap..... 500 grammes.
Finely pulverized pumice-stone... 250 grammes.

3. Daily antiseptic inunction with the following mixture:

℞. Resorcin..... 5 to 10 grammes.
Ol. ricini..... 45 grammes.
Spt. vini rect..... 150 grammes.
Bals. Peru..... 0.50 centig.

or

℞. Acid. salicylic..... 2 to 3 grammes.
Sulph. precip..... 10 to 15 grammes.
Lanolin..... 70 grammes.
Vaseline..... 18 grammes.

Revue Gén. de. Clin. et de Thérap., No. 49, 1891.

The Medical Treatment of Appendicitis.—In a paper recently read at the Philadelphia County Medical Society, Dr. Kirkpatrick said: "I believe most cases of obstruction of the bowel, if not due to intussusception or strangulated hernia, are due to the absence of the natural secretion caused by the localized typhlitis, which, if not soon relieved, becomes a perityphlitis, and then more or less general peritonitis must result. The rational method

seems to me to be: 1. To relieve the pain by hypodermic injections. 2. To remove the cause or obstruction by causing, if necessary, pathological or excessive secretion, by giving some saline, which I believe is the best antiphlogistic for the inflamed bowel. 3. To soften the hardened fecal accumulation from below with enemata, solution of Epsom salts in water as hot as can be comfortably borne, to which I add turpentine and oil. The knee chest position, with copious enema, favors the distention of the colon up to the seat of the disease. I have found by experience that the enema to be effective must be given in this position, and that it must remain in the bowel for some time, and in several of my cases it was necessary to repeat the operation three or four times. This plan of treatment has been successful in six cases, which are all that I have treated; but I fully realize that it may fail in the seventh."

Typhoid in Infancy.—Dr. Jules Simon prescribes for the agitation in typhoid of infants:

℞. Hydrate chloral..... 0.50 cigr.
Tinct. moschi..... gtt. xx.
Aq. tiliæ..... 80 grammes.
Syr. aurantii flor..... 20 grammes.

M. S.: To be taken during the twenty-four hours in dessert-spoonful doses.

—*Gaz. Méd. de Liège.*

Chloral in Pneumonia.—Dr. Balfour (*Edinburgh Medical Journal*, November, 1891) says it would not be easy to find another drug with a concatenation of properties so suitable for the treatment of pneumonia as those which chloral possesses. It slows the heart by paralyzing the cardiac ganglia, and it dilates the arterioles by paralyzing the vaso-motor centres. It is hypnotic, analgesic, and it diminishes and ultimately abolishes all the reflexes, while the antipyretic action is in the right direction. Besides soothing pain, stopping cough, and relieving insomnia, chloral really seems to shorten the duration of the disease or favor an early crisis. No chloral excepting Liebreich's is considered safe, and the author combines it with digitalis, giving for the first dose twenty grains of chloral in half an ounce of infusion; the subsequent dose being ten grains in half an ounce of infusion every four hours till the temperature falls to normal. Of course the dose is to vary with the patient's age.

Function of the Tonsils.—Dr. Gulland (*Edinburgh Medical Journal*, November, 1891), from a study of the interesting question relating to the use of the tonsils, draws the following conclusions: 1. The tonsils—faucial, lingual, and pharyngeal—are organs arranged to further the reproduction of leucocytes. 2. This reproduction takes place, mainly in the germ-centres, by mitotic division of pre-existing leucocytes. 3. The young leucocytes so formed are partly carried off to the general circulation by lymphatic vessels originating in the tonsil, partly remain in the tonsil as "stationary" cells, and partly wander out into the crypts by perforating the epithelium. 4. They thence pass to the surface of the tonsils, and take up foreign bodies, especially micro-organisms, which would otherwise pass the tonsils. 5. In the human subject the lingual and faucial tonsils, and the slight diffuse leucocyte infiltration of the under surface of the velum palati, form a protective ring or zone between the mouth, which abounds in microbes, and the rest of the alimentary tract; while the pharyngeal and tubal tonsils, and the diffuse leucocyte infiltration of the upper surface of the palate, form a protective ring round the upper part of the respiratory tract. 6. There is no reason to regard the tonsils as having any absorbent function in normal circumstances; the reproduction of leucocytes is sufficiently active, as a rule, to keep up a continuous outward stream of these cells, and to prevent the entry of foreign substances into the tonsils. 7. Under certain circumstances—for instance, in general debility—the reproduction of leucocytes may be interfered with, and the outward stream of these cells from the tonsils may be arrested. This arrest or other circumstances interfering with the activity of the leucocytes, may allow pathogenic organisms from the mouth, etc., to enter the tonsil by the spaces in the epithelium, and these microbes may give rise to a local or general infective process.

Bromo-potassic Stomatitis Cured by Chlorate of Potassium.—In the *Gazette des Hôpitaux*, December 31, 1891, Dr. E. Marandon reports two cases of stomatitis induced by bromide of potassium, analogous to mercurial stomatitis, in which a cure was effected by chlorate of potassium. Age, sex, season, temperament, apparently were not factors, for the patients differed widely in physique and original abnormity. One was a poorly nourished neurotic, recovering from depressive melancholia. The other, a strong, robust girl, was subject to attacks of epilepsy. Both had neuropathic ancestry, and both suffered from an exactly similar form of stomatitis. The dento-alveolar regions were most affected. About the lower teeth, which were excellent in both instances, the gums were particularly red, inflamed, sensitive, and bled easily. There was present the characteristic and constant fetid breath of bromide of potassium, a bitter, profuse silalorrhœa, which is rare. This condition of stomatitis is exceptional, and is due rather to reflex action than to direct poisoning. The observer inclines to the belief that the glands about the gums are the only ones in the mouth that eliminate bromide of potassium. The drug was stopped, chlorate of potassium given as in mercurial stomatitis, and the trouble disappeared in two weeks. In six days there was marked improvement.

Cutaneous Absorption.—As a result of some researches recently made by Guinard and Bouret (*Journal de Pharm. et de Chimie*, 1891) to determine the cutaneous absorption of medicinal substances incorporated in fatty bodies, the conclusion is reached that: 1. The intact skin does not absorb substances incorporated in fats, or, if it does absorb them, it does so only very slowly and in infinitesimal proportions, and only in hairy regions. 2. That the excipients axunge, vaseline, and lanoline present no differences, no advantages the one over the other so far as the penetration of a drug through the epidermis is concerned. Repeated experiments on frogs showed that strychnine in vaseline produced toxic effects and death more quickly than when incorporated with lanoline. Other laboratory experiments lead to the same result. The authors therefore conclude that, if a pomade is to be employed with the view of causing absorption of an active principle, the excipient to be preferred is vaseline. If, on the other hand, we desire a local action on an absorbent surface (denuded skin, ulcer, wounds, etc.), axunge will prove better, for this substance will maintain the drug longer where we want its action. A rapid and energetic local surface action, however, such as a parasiticide action, is best accomplished by vaseline.

New Reaction for Albumin.—Dr. Jolles gives, in the *Zeitschrift für Anal. Chem.*, No. 29, a new test for albumin, and a method of detecting minute quantities in the urine. Eight to ten cubic centimetres of urine are treated with an equal volume of concentrated hydrochloric acid. Then add carefully without shaking, by means of a pipette, two or three drops of a saturated solution of chloride of lime. At the limit of separation of the two fluids a white line is formed, even when as little albumin is present as 0.01 per cent. A better method for traces of albumin is that by acetic acid and ferrocyanide of potassium; even with this test, which shows as minute a trace as 0.0008 per cent., if bacteria are present the reaction is marked. It is well known that filtration does not render the urine clear under these circumstances. The result can be accomplished, however, by first shaking the urine with sand, but in this case the albumin may remain with the precipitate. In such event the precipitate is washed with hot caustic soda, neutralized, and treated as before.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, February 6, 1892.

THE ORIGIN AND UNCERTAINTY OF SPECIFICS.

IN the "Practical Manual of Diseases of Children," Dr. Edward Ellis calls the attention of his medical brethren to an elucidation of the apparent mysteries attending the trial of valuable drugs in diseases of certain names. Much vaunted as powerful to cure positively, these remedies too often fail in spite of statistics, proving that nothing can lie like figures except facts. The proposition enunciated by Dr. Ellis is this: A disease may exist, *per se*, originated in the healthy organism by some specific cause at present unknown, said to be cold, strain, atmospheric condition, etc., but the actual cause in reality a perfect mystery. A fine specimen of an acute type of disorder appears as pictured in the text-books and runs its respectable and time-honored course according to classic lines. This is a disease easily curable, for it tends to cure itself. Unless the physician interferes too much, the type of disease under consideration, whether pneumonia, acute rheumatism, or what not, under ordinarily favorable circumstances will resolve and get well. This furnishes a list of cases that vaunters of specifics exult over. Having looked on this picture, turn now to another.

There is a still more serious class of cases, far more common, and which bear similar names. They are the final outcome of widely divergent conditions, in which, by a mere accident, as cold, strain, weather, the actual attack is determined. The patient, perhaps, is long getting ill, is down in his physical luck, decidedly below par in various ways. This continues for a time, during which medical advice is seldom sought. Then some accident overthrows everything. This form of illness, no matter what its name, whether malaria, so-called, pneumonia, or acute rheumatism, is very rarely amenable to specific treatment. The vaunted remedies fail, and only a careful consideration of the patient as a unique entity, and not as the exponent of a class, will direct the physician to any kind of success. The origin and uncertainty of specifics are alike matters of chance in the majority of instances, and under circumstances wherein anything in reason would have hastened the cure. The advice of an experienced physician to his younger colleague, to the effect that new remedies must be avoided if he would succeed, contains more than the usual grain of wit and wisdom.

SHOULD LEPERS BE ISOLATED?

THAT it is sometimes necessary to sacrifice the individual for the sake of the community, when the interests of the two are in conflict, is one of the hard conditions of human society upon which its very existence depends. Yet society does not willingly sacrifice the individual, and is always jealous in protecting his rights as against itself. It shuts up the dangerous lunatic and the murderous criminal, and isolates those who are sick with actively contagious disease; yet it hesitates, sometimes too long, before pronouncing a lunatic dangerous, it gives the criminal every possible chance to escape the law's clutches, and it does not willingly stamp a disease contagious enough to demand the isolation of the sufferer from it. It is perhaps owing to this regard for individual rights that, in the matter of isolating the sick, society is often inconsistent. It separates from the community the sufferer from small-pox, or scarlatina, or typhus fever, but the syphilitic and the tuberculous it leaves free to spread contagion where they will. It is curious, indeed, that the community protects itself in this way only from acute diseases, and, either through ignorance of their infectious nature, or through reluctance to condemn the sufferer to long, perhaps life-long, separation from his kind, it takes no such precaution against chronic disease.

The only exception to this rule is in the case of leprosy, and this is one of the inconsistencies to which we have just referred. Even admitting that leprosy is a contagious disease, which has been denied by some eminent authorities, no one would class it in this respect with small-pox, yet the discovery of a single leper in a community like New York excites perhaps more alarm than does that of half a dozen cases of small-pox, as has been exemplified in this city within the past six months. This is doubtless due in great measure to the scriptural tradition of leprosy and the accounts there contained of its sudden onset, its malignancy, and the hopeless condition of its victims. It is, of course, known to the profession that there were several diseases of very different characters included under the biblical term leprosy, but the laity know only the name, and clothe the disease with all the horrors which are attributed to it in the Jewish chronicles.

And this leads to the question which heads these lines Should lepers be isolated? If the disease is certainly not contagious then it is a most cruel thing to cast out its victims from society. It is surely enough to suffer from a loathsome and practically, as yet, incurable disease without the additional horror of becoming an outcast, of being separated from all companionship with friends and relatives, and of being condemned to pass the remainder of a wretched life in the society of other miserable sufferers. Yet, on the other hand, if leprosy be contagious the community must protect itself by isolating the leprous. At present this is a moot question, and one concerning which much can be said on both sides. Many recognized authorities assert without reserve that it is contagious, and maintain that the only safety to the community lies in the prompt isolation of the sick from the well. Yet it is only a few weeks ago that so eminent a dermatologist as Dr. Bulkley, of this city, read a paper before the County Medical Society in which he held that the disease was

not contagious, or at most that the degree of contagiousness was extremely small. And these views were seemingly acquiesced in by those who discussed the paper. Nevertheless society cannot imperil itself on the strength of what is as yet only a theory, and although the event may prove that it has inflicted unnecessary hardship, we believe that it ought not to permit lepers to live where they come in daily contact with the well, at least not until the true cause of the disease has been discovered, or until it has been conclusively proven that it cannot be spread in this manner.

THE NEW HEALTH OFFICER.

The appointment of Dr. William T. Jenkins as Health Officer of the Port of New York is an eminently fitting one and will give great satisfaction to the medical profession and the public. His previous record as a public officer in connection with the coroner's office, and his reputation as an able medical man are unquestioned, and carry with them the conviction that the duties of the new office will be ably, energetically, and conscientiously discharged. As a member of the Health Board of this city, Dr. Jenkins will also be an acquisition, and will bring to that position an official experience which will be of great service to the community. We congratulate him on the honor so worthily bestowed, and on behalf of his numerous professional friends wish him the highest measure of success.

THE RECENT POISONING CASE.

The trial of medical student Carlyle W. Harris for poisoning his wife with morphine, which terminated during the past week in a verdict of murder in the first degree, has commanded more than the usual amount of public attention in consequence of the interesting questions involved in the medical jurisprudence of the case. The legal talent on both sides was displayed in a remarkably brilliant manner, and both Mr. Wellman for the prosecution, and Mr. Jerome for the defence, have won for themselves enviable positions in their profession. It was due to their successful efforts in working up their respective sides that many novel theories in regard to morphia-poisoning were brought forward for the consideration of the medical experts. As might have been anticipated it was not difficult to make these experts flatly contradict each other on essential points, and thus hopelessly muddle the unscientific brains of the jury. But this display of contradictory evidence was not without its lesson to the student of medical jurisprudence in emphasizing the necessity of impartial scientific commissions, whose functions should be advisory and explanatory to the court, as opposed to the custom of experts who are avowedly engaged to take one side or the other.

In commenting upon the case from a scientific point of view it is fair to say that the evidence clearly pointed to morphia as the cause of the victim's death, notwithstanding the able testimony to the contrary offered by gentlemen of acknowledged experience in pathology and the micro-chemistry of poisons. It was also plainly to be seen that pathological lesions, claimed to have been possible in the brain and kidneys, could not be demonstrated weeks after the burial, and when decomposition had commenced. Although a motive for the murder was demonstrated, the proof that the victim was given a dose by the prescriber sufficient to kill was purely presumptive and circumstantial. The quantity alleged to have been given was an ordinary dose of morphine at reasonable intervals. The theory that one or more of the capsules containing the mixture of quinine and morphine, as compounded by the pharmacist, was emptied by the defendant, afterward filled with morphine, and then administered to the victim, was not substantiated by any facts brought out by the prosecution. This was the only probability that could be entertained to make the necessary connecting link of cause and effect in constructing the strong and damaging chain of circumstantial evidence against the accused.

THERAPEUTICS OF CHLORANÆMIA.

The gastro-intestinal troubles of chloranæmia, as dilatation of the stomach, ancholorhydria or hypercholorhydia, and habitual constipation, have long been recognized and treated more or less wisely, up to the present time, by means of general intestinal antisepsis and the systematic administration of purgatives. In Nothnagel's clinic in Vienna, Dr. Pick reports the best results are obtained by lavage of the stomach, fasting. In other cases where this procedure is refused, he suggests the use of creosote, one gramme to be mixed with six of sugar of milk. This is then divided into twenty powders, of which one is taken three times a day.

CREOSOTE IN INFLUENZA.

French journals recommend five-centigram pills of creosote in rhinitis and laryngitis due to grip. Twenty or thirty may be taken a day, as many as one hundred in six hours having been administered in a certain instance.

LOVE AND THE DOCTOR.

Some very clever verses with this title appear in the *Journal d'Hygiène*, October 22, 1891, in which the similarities and differences of the merciless god and the modern physician are carefully summed up. Both are on duty day and night. "And this is a resemblance," together with the fact that each is blind. One is famous in old age, the other in youth. "And here is a difference." One feels the pulse, the other touches the heart. Each is something of a charlatan. "*Voilà la ressemblance!*" One leaves when we are doing well, and the other departs in time of stress. "*Voilà la différence!*"

A NEW INTESTINAL ANTISEPTIC.

MM. Yvon and Berlioz, writing on the above subject in the *Practitioner* of December, 1891, say: "For some time past practitioners have been using a combination of β-naphthol with salicylic acid, as a substitute for the former body. The combination is known as the salicylate of naphthol, or, briefly, betol, but its composition is not constant, and it does not meet all the therapeutic requirements of the cases in which it is employed. In cer-

tain cases where renal disease exists, the kidneys are injuriously affected by the elimination of the salicylic acid, due to the breaking up in the system of the salicylate."

The writers believed that they could make a safer combination by uniting beta-naphthol with benzoic acid, a drug which is less toxic than salicylic acid, less injurious to the kidneys, and a more powerful antiseptic.

The benzoate of naphthol, or benzo-naphthol, is a whitish powder without taste or smell, insoluble in water, and but slightly soluble in alcohol. When introduced into the alimentary canal it breaks up into beta-naphthol and benzoic acid. The conclusions drawn from a not very extensive use of the drug are :

1. That it is very slightly toxic.

2. Its antiseptic power is comparable with that of the other substances employed in promoting intestinal anti sepsis.

3. It promotes diuresis, and dimiuishes the toxicity of the urine.

4. The portion of it which is absorbed is easily and rapidly eliminated by the kidneys.

5. The dosage may be rapidly raised for adults to 5 grammes (75 grains) a day, and for children to 2 grammes (30 grains) a day. It should be given in small quantities frequently repeated. A dose of about 25 to 50 centigrammes (4 to 8 grains) in wafer-paper, or suspended in a convenient vehicle (syrup and water, for example), suffices in the majority of cases.

Benzo-naphthol seems to possess all the characters of a good intestinal antiseptic. The gentlemen who recommend it, however, ignore the fact that the naphthol is to some extent absorbed and can cause toxic symptoms. We have had so many intestinal antiseptics from the laboratories of Paris, which have turned out to be of little value, that the profession is getting sceptical of new claimants, however strongly endorsed.

THE REGULATION OF MEDICAL PRACTICE IN WASHINGTON.

In the *Virginia Medical Monthly* for December, 1891, Dr. Robert T. Edes discusses the subject of "The Regulation of Medicine in the District of Columbia," and gives the text of two bills which have been introduced into Congress for the purpose in question. Each of the bills provides for the appointment of a Board of Medical Examiners, and it is with regard to this point that, as usual, trouble arises. The District Medical Society's bill provides for a board of nine physicians, five nominated by the Society, two by the Homœopathic Medical Society, and two appointed "at large." The other bill provides for a board of fifteen, of whom eight are to be regular physicians, five homœopathic, and two eclectic.

The curious part of this feature is that, as a matter of fact, there are in Washington 444 regular physicians, 36 homœopathics, and 2 eclectics, giving a proportion of 222, 18, and 1, or 13, 1, and $\frac{1}{8}$.

This bill is another illustration of the well-known fact that "schools" of medicine now keep up organization chiefly for what there is in it, not because they embody scientific truths.

Sir Richard Quain's wife has recently died from shock following an operation.

THE HEALTH OF THE SURVIVORS OF THE WAR.

A recent article in *The Forum* on the health of the survivors of the war, by Dr. John S. Billings, contains some facts of interest.

The total number of soldiers enlisted in the United States Army was about 2,100,000. During and since the war one million have died. The death-rate during the war was about eighty-eight per thousand. Fifty-five in a thousand died of disease, thirty-three of injury. Since the war the annual death-rate has been about fourteen per thousand, which is a little above the average for adult males. Deaths occurred pretty rapidly for a few years after the war, but after that the per cent. fell. At present, the investigations as to the health of the survivors of the war show that the sick-rate is about four times greater than it is among the ordinary population. This is not surprising, unless the comparison be made between the health of the veterans and that of the adult male population over fifty years of age, for the great majority of war veterans must have passed that age.

News of the Week.

A Census of Hallucinations.—The New York branch of the American Society for Psychical Research will be addressed by Professor William James, of Harvard University, on the evening of February 10th, at 8 P.M., at Room No. 10, Columbia College (Law Buildings), on the subject of "A Census of Hallucinations," and also Dr. Hodgson, Secretary of the American Society, on "Automatic Writing." Admission will be free, but by ticket only. Tickets may be obtained on application to the Vice-President and Secretary of the New York branch, Dr. James H. Hyslop.

New York County Medical Association.—At the annual meeting of this Association, held January 18, 1892, the following officers were elected: *President*, S. B. Wylie McLeod, M.D.; *Vice-President*, William T. White, M.D.; *Recording Secretary*, P. Brynberg Porter, M.D.; *Corresponding and Statistical Secretary*, Augustus D. Ruggles, M.D.; *Treasurer*, John H. Hinton, M.D.; *Member of the Executive Committee*, Beverhout Thompson, M.D. The Association now has more than seven hundred members on its roll.

The Cincinnati Obstetrical Society, at its annual meeting, elected the following officers for the ensuing year: *President*, Dr. Byron Stanton; *Vice-President*, Dr. Gustav Zinke; *Secretary*, Dr. E. S. McKee; *Corresponding Secretary*, Dr. C. A. L. Reed; *Treasurer and Librarian*, Dr. George E. Jones. On motion of Dr. Giles Mitchell, the Society declined to banquet on the evening of January 28th. The next regular meeting will be held at the residence of the retiring President, Dr. E. W. Mitchell.

Movable Kidney.—Dr. A. MacSwain, formerly of Riverside, now of Santa Clara, Cal., was operated on for a movable kidney by Dr. C. O. Baker, of Auburn, N. Y., on January 18th. The operation promises a perfect result, and will be fully reported later on, as it is one of more than usual interest.

Dr. John W. Dowling, a well-known homœopathic physician of this city, died recently.

Dr. Charles Martin, Medical Director, United States Navy, died at his home in this city on January 14th. Dr. Martin, after thirty-six years of long and active service, was retired in 1884.

Censorship of Medical Journalism in Russia.—The Society of Physicians of Odessa applied for permission to publish a medical journal "without previous revision by the Censor," but the Minister of the Interior having declined to sanction the publication, the Censor must pass upon the merits of the manuscript before it goes to press.

The Alkaloid of Lactuca Sativa.—It has long been believed that the common lettuce contained an alkaloid, since attention has often been directed to its mydriatic action on the eye of those who indulge somewhat inordinately in lettuce salads. The students of the Research Laboratory of the Pharmaceutical Society have at length succeeded in eliminating the alkaloid in the form of flat needle crystals, closely resembling those of hyoscyamine. Both the wild and garden varieties of lettuce yield the same alkaloid, and it is found in somewhat larger quantities when the plant is in flower, 0.02 per cent. So small a percentage is, however, of no great importance in connection with the use of the plant as a vegetable, since it is always brought to the table in the early stage of its growth, and rarely or never when the plant is about to flower.—*Medical Press.*

Dr. W. H. Hingston, of Montreal, has been appointed to deliver the address on Surgery at the next annual meeting of the British Medical Association, to be held in Nottingham.

Opening of a Hospital in Bokhara.—On the Czar's name-day in Bokhara the first public hospital, a gift from the Amir in commemoration of the escape of the Czarewitch in Japan, was opened with great ceremony in the presence of the Russian diplomatic agent, the Russian colony, and the representatives of the vassal Ruler of the Khanate.

Association of Acting Assistant Surgeons of the U. S. Army.—We are sorry to see the letter-head of this organization and the signature of its Recorder made use of as a display advertisement of a porous plaster in the daily papers.

The North London Medical and Chirurgical Society was established about two months ago, with a membership of one hundred and fifty.

A New Leper Hospital in Russia.—According to the *British Medical Journal*, the first leper house in the Baltic provinces in Russia was recently opened at Riga. It is intended provisionally to accommodate twenty men and as many women. The medical and administrative staff live in a separate building, and to lessen the risk of infection the attendants live as far as possible apart from the patients. Dr. A. Reisner is the medical officer in charge, and the institution is under the general supervision of Dr. A. Bergmann, to whose initiative and persevering efforts its establishment is principally due.

Hypnotism in Belgium.—The Belgian Parliament has recently passed a law restricting the practice of hypnotism, and forbidding the public exhibition of any hypnotized person. The punishment for exhibiting any hypnotized individual is imprisonment for from two weeks to six months, and a fine of from 20 francs to 1,000 francs. No one, not a physician, is permitted to hypnotize any minor or person of unsound mind, the penalty for so doing, even when the person is not exhibited, being a fine of from 20 francs to 1,000 francs. It also punishes with imprisonment any person who, with the intention of cheating or otherwise injuring, causes a hypnotized individual to sign a paper containing a contract, disposition, obligation, release, or declaration of intention. The person deriving benefit from such a paper is liable also to the same penalty.

A New Foundation for a Hospital in Odessa.—A Mme. Wallich, who died not long ago in Nice, has bequeathed about $60,000 to the municipality of Odessa for the purpose of erecting a new hospital in that city.

Railway Casualties.—The total number of persons reported killed on the railroads of the United States during the year ending June 30, 1890, was 6,334, of whom 2,451 were employees, 286 were passengers, and 3,597 were classed as "other persons," including tramps stealing rides, persons run over, and suicides. The total number reported injured was 29,025, of whom 22,394 were employees, 2,425 were passengers, and 4,206 were unclassified. Fewer passengers, but more employees, suffered casualties than in the previous year.

Increasing the Tax on Cigarettes.—One of the methods which have been proposed to restrict the sale of cigarettes to boys is to levy an increased tax under the internal revenue laws. The tax is now only fifty cents a thousand, and if this were raised to $8 a thousand, the cost of the cheapest cigarettes would be doubled. The sale would in consequence be so restricted that the manufacturers would probably find it unprofitable to make any but the finest grades, and the high price of these would put them way above the reach of most boys. The law forbidding the sale of cigarettes to children under sixteen years of age, is disregarded and worse than ineffectual, as all laws are that are not enforced.

New York State Commission in Lunacy.—The following are some of the orders recently adopted by this body, relating to the reception of pay patients in the State hospitals for the insane, to the employment of physicians in licensed institutions for the treatment of the insane, and to the admission of voluntary patients in those institutions which are permitted to receive them as well as committed patients. That no license will hereafter be granted to operate and maintain an institution for the care, custody, or treatment of the insane, unless such institution shall be constantly in charge of a well-educated resident physician (to be designated "Physician in Charge"), who must be a graduate of a legally incorporated medical college and must have had at least five years' actual service as a physician in an institution for the care and treatment of the insane. In existing institutions this order will in all future appointments be held to apply. That hereafter the approval of the Commission in writing will be required upon the appointment of all assistant physicians in licensed institutions for the care, custody, or treatment of the insane. In existing institu

tions this order will in all future appointments be held to apply. That no voluntary patient shall be admitted to a licensed institution for the care, custody, or treatment of the insane permitted to receive voluntary as well as committed patients, whose mind is so impaired as to render him incapable of forming a rational judgment as to the disposition of his person, or whose will is so weak as to render him incapable of resisting undue influence, nor unless an application for admission is made in the form prescribed by the Commission. That all persons committed to any institution for the care, custody, or treatment of the insane must, at the time of admission, be informed by the receiving medical officer of the character of the institution and the cause of detention.

Influenza in London.—The influenza continues to spread, and the mortality from it is on the increase. During last week two hundred and seventy-one deaths were registered as primarily due to it, and in sixty-three cases it was registered as a complication occurring in the course of some other disease. As in the previous epidemics, the mortality is highest among elderly persons. Many fatal cases have, however, occurred among the young, and at Oxford, where the disease is very prevalent at present, the university authorities are so impressed with the gravity of the situation that they have postponed the commencement of Lent term until the end of the first week in February. Concurrently with an increase in the mortality from influenza has been a rise in the death-rate from respiratory diseases in general, and in London last week no fewer than 1,248 deaths were registered as due to diseases of the respiratory organs, being nearly double the average. High death-rates have also prevailed in several of the provincial towns.

The Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons for 1892 will be delivered at the New York Academy of Medicine, No. 17 West Forty-third Street, February 12th, 19th, and 26th, at 8 P. M., by Professor Henry F. Osborn, of Columbia College. Subject: Present Problems in Evolution and Heredity. 1. The Contemporary Evolution of Man. 2. The Difficulties in the Heredity Theory. 3. Recent Studies upon the Germ-cells. The profession is invited to be present.

What Must They Use?—It is said that down in Kentucky the physicians treat the grip as if it were a severe case of snake-bite.

State Mortality Statistics.—The State Board of Health, on February 1st, issued the monthly mortality bulletin for the month of December, and also a summary of the mortality statistics for the year ending January 1, 1892. The former shows the total number of deaths for the month of December, 11,241, of which the greatest number was caused by acute respiratory disease, which number was 2,731; lowest, cerebro-spinal fever, 32. Of the total, 3,023 were under five years of age. The average for the past six years has been 8.992. The greatest per cent. per 1,000 inhabitants was at Courtland, where it reached 44.64 per cent., and Cohoes second, where it was 38.91 per cent. The summary for the year shows the following: Number of deaths in each of the twelve months: January, 9.548; February, 8,704; March, 10,672; April, 13,931; May, 10,213; June, 9,321; July, 11,370; August, 10,720; September, 9,662; October, 9.718; November, 8.878; December, 11,241. They occurred in the eight districts as follows: Maritime, 74,681; Hudson Valley, 12,209; Adirondack and North, 4,131; Mohawk Valley, 5,978; Southern tier, 4,648; East Central, 5,113; West Central, 4,040; Lake Ontario and Western, 12,928.

Dr. Albert T. Weston has been appointed Coroner Levy's assistant, vice Dr. W. T. Jenkins, resigned. Dr. Weston was Coroner Shultze's physician until January 1st, when Dr. Walsh, the present incumbent, succeeded him.

Death of Dr. David Fleischman.—Dr. David Fleischman died at Albany, N. Y., January 30, 1892. He was born March 12, 1859. Graduated with prizes and honors from Yale College in 1879 and from Albany Medical College in 1881. Pursued post-graduate course in New York, at Post-graduate School, and under Bosworth and Jarvis, and followed the practice of specialty of Laryngology and Rhinology in Albany since 1883. He was esteemed by the entire profession in his vicinity for his ability and exceeding modesty, commanded the respect of everyone, and was the idol of his patients. He was a type of the true physician. A year ago a severe attack of "la grippe" paved the way for pleurisy, which in turn was followed by a fatal attack of tubercular meningitis.

Obituary.

SIR MORELL MACKENZIE, M.D.,

LONDON, ENGLAND.

THE cable announces the death of Sir Morell Mackenzie, M.D., which took place in London on the evening of February 3d. He was born in Leytonstone, Essex, in 1837, and was educated at the London Hospital Medical College and the Paris and Vienna universities. He founded the Hospital for Diseases of the Throat, in London, in 1863, and at about the same time obtained the Jacksonian prize from the Royal College of Surgeons for his essay on diseases of the larynx. Somewhat later he was elected assistant physician to the London Hospital, at which he subsequently became full physician and lecturer on diseases of the throat. He was a corresponding member of the Imperial Royal Society of Physicians of Vienna, and of the Medical Society of Prague, and an honorary fellow of the American Laryngological Association. He was the author of numerous smaller works on laryngological subjects, of monographs on diphtheria and hay fever, and of a standard book in two volumes on "Diseases of the Nose and Throat." Dr. Morell Mackenzie was knighted in 1888 as a reward for his attendance upon the Crown Prince of Germany during that distinguished patient's long and eventful illness. As usual under such circumstances, when so much was at stake as to royal succession, depending upon the question as to whether or not the disease was necessarily fatal, the physician in charge became involved in an international court intrigue, which for a time imperilled his fair fame as a scientist and honorable gentleman. He, however, conducted himself with great prudence and discretion, and returned to his home honored by his sovereign and respected by his many friends. Soon after his return to London his health began to fail, a cough developed, and progressive tuberculous disease of the lungs finally caused his death. Shortly after he had been knighted Sir Morell Mackenzie published his defence in a book entitled "The Fatal Illness of Frederick the Noble."

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-sixth Annual Meeting, held at Albany, February 2, 3, and 4, 1892.

A. Walter Suiter, M.D., President.

First Day, Tuesday, February 2d.

President's Inaugural Address.—The President took a hopeful view of the progress of medical science. Referring to codes of ethics, he expressed the view that they would soon be things of the past, unworthy a place in these days of advanced and rapidly advancing civilization. The dawning of a better and brighter day was at hand.

The Address then discussed points concerning the volume of Transactions, and then passed to a review of facts brought out by State Medical Examining Boards, regarding the number of medical colleges in this country and Canada, the increasing number extending their courses, etc.; while the three boards of examiners in New York had worked harmoniously, yet the present indications pointed to the advantage and likelihood of their consolidation into one board.

He favored action by the Society requesting of the Legislature increased appropriation for the State Medical Library.

Reference was also made to the Pan-American Medical Congress to be held at Washington, 1893.

He said the suggestion had been made that retired surgeons of the United States Army, past Major, all be made honorary members.

The President also called attention to the well-known abuse of medical charity at hospitals and dispensaries.

The deaths of honorary and permanent members during the year had been unusually large.

A committee of three was appointed to report on the recommendations contained in the Address.

On motion of Dr. Roosa a specialty committee of five, to be appointed by the President, was empowered to name at least four persons, from whom the Society should select two, to act, by appointment of the Board of Regents, on the State Board of Medical Examiners. This motion received some opposition by those who wished the nominations to be made by the regular Nominating Committee.

A Plea for the Methodical Treatment of Chronic Diseases.—Dr. Simon Baruch read in abstract a paper on this subject, taking as illustrative diseases phthisis, gout, rheumatism, gastric ulcer, and diabetes. He wished to impress, as the title of the paper indicated, the desirability of methodical treatment in chronic cases, which modern science had taught us to apply with so great advantage in acute diseases. In acute diseases we had found that, as a rule, best results were obtained from methodical management. A general panacea was no longer sought. There was no doubt but what phthisis could be cured, and its cure did not depend upon attitude, climate, etc., but upon systematic out-of-door life in an atmosphere free from dust and injurious substances. Yet, as long as active inflammation existed the lungs should be kept at rest. The methodical treatment also involved the judicious use of the bath, of diet, etc. The same remarks applied to other chronic diseases.

Until we should come to dose our exercise, etc., the same as we did our medicines, and see that the prescription was followed to the letter, we would not get precision in our results. Referring to a work by Dr. Weir Mitchell, he said this eminent scientist had immortalized himself by simply applying principles which the reader was then urging upon our attention in other diseases, namely, a more methodical application of our remedial measures, chiefly dietetic, hygienic, and psychic.

Dr. J. Leonard Corning applied the principles laid down by Dr. Baruch in many cases of nervous exhaustion. It required discrimination in applying enforced rest in bed in nervous cases, or the so-called Weir-Mitchell treatment, for he had known persons made much worse by it, indeed driven almost to insanity. Greater benefit, as a rule, was obtained by an extra number of hours of sleep.

Dr. Ransom, Dr. Bulkley, and others emphasized the value of methodical treatment in chronic cases. Dr. Bulkley had kept notes regularly of chronic cases, as he did of acute ones, which he regarded as the only possible way to keep track of the progress of chronic diseases, and thereby enable him to apply his remedial agents intelligently and effectually.

A Case of Pneumo hydrothorax.—Dr. Eugene Beach read the history of the case, which occurred in a patient who had lesions of phthisis. Replying to the statements of Dr. Flood, made during the discussion, that almost invariably the fluid in the pleural cavity in cases of pneumo-thorax was purulent instead of serous, he said no autopsy was made in this case, nor was any of the fluid withdrawn, yet the physical signs pointed clearly to the presence of air and fluid, and there had been, two months prior to the bulging of the chest, no temperature pointing to empyema.

Dr. Ralph Waldo had seen a case of pneumo-hydrothorax when interne in Charity Hospital. Serum was aspirated. But at autopsy it was found to have become purulent, owing, he thought, to the puncture.

Perforation of Typhoid Ulcer with Adhesive and Protective Peritonitis.—Dr. H. L. Elsner, of Syracuse, described the case, which occurred in a man who entered the hospital probably at the second week of "walking typhoid." The treatment was expectant. After about two days the symptoms suddenly changed, becoming those of intestinal perforation. The absence of McBurney's point, taken with the history, appendicitis was excluded. The local symptoms were those of tympanites below, dulness over the liver, apparent tumor, pain over this tumor.

The patient had considerably improved within a few days, and could be exhibited before the class. On the tenth day there was again a sudden change, the patient had several bloody fecal discharges, and died. The autopsy showed slight adhesion of a coil of the ileum to the colon, which, when turned over, allowed the escape of gas. An opening was then seen, two millimetres long, at the seat of a typhoid ulcer. Most of the adhesive inflammation was in this locality, and with an adhesive band contributed to the tumor. Intestinal contents had not escaped.

His conclusions were: 1, a local peritonitis might shut off the perforation; 2, in some cases coils of intestine might become adherent and form an apparent tumor; 3, appendicitis might be closely simulated; 4, liver dulness was to be accounted for by gas being confined below a line of adhesions; 5, an operation was not desirable where a protective process was evident.

Dr. A. Jacobi drew from the case a practical lesson, namely, in all cases of typhoid fever and intestinal catarrh, avoid a chronic condition by active treatment as opposed to the expectant, which too often meant entire neglect of the case. As a result of such neglect, perforation was liable to take place at some future time in the weakened point left by the inflammation.

Dr. Chefsman related a case of typhoid in a child, followed by gangrene of the umbilicus, and one in a man, followed by several attacks of orchitis.

A Pathological Review of Diphtheria, with Special Reference to a New Method of Treatment.—Dr. F. E. Martindale, of Port Richmond, in this paper worked his way up to the view that the profession had a sure cure for diphtheria in an atmosphere containing the vapors of tar and turpentine, if treatment were begun before the disease had become constitutional. He had

within three years treated 24 cases, losing but 1, which he saw in consultation on the fifth day after the development of severe constitutional symptoms. He regarded the disease as of microbic origin.

Asepsis and Antisepsis in Obstetric Practice.—Dr. George Seymour in this paper advocated the principles of asepsis, and also of antisepsis, with a view to securing as nearly as possible absolute cleanliness in all cases of labor. Unfortunately, fifty per cent. of women were attended in their confinements by midwives, who, of course, did not apply the principle becoming so generally appreciated by medical men. The author gave details as to furniture in the room, cleansing of person and instruments, use of bichloride or creolin solution as antiseptics in washing hands, vulva, etc.

Dr. Currier thought that in private practice it would be difficult among the poor to establish very nearly the conditions of the laparotomy room as advocated by the author, and among the wealthy who were cleanly in their habits it was not so necessary.

Dr. Baruch called attention to Leopold's present practice of allowing no vaginal examination in uncomplicated cases.

Peculiar Case of Chronic Ascending Anterior Poliomyelitis.—Dr. C. E. Lockwood, of New York, read the history of the case. The symptoms for some time were limited to the distribution of the anterior tibial nerve; began after slight traumatism; was regarded at first by Dr. Hamilton and Dr. Starr as a peripheral neuritis, then passed to other parts, involving muscles of both legs and upper extremities; finally, after two years, terminated in death by involving the respiratory centre in the medulla oblongata. The reaction to galvanism further made the case resemble the peroneal type of progressive muscular atrophy, as described by Charcot and others. The microscopic examination of the cord confirmed the diagnosis indicated by the title.

Dr. A. Jacobi advocated more heroic use of sulphate of strychnia, and administered it hypodermically. He had given as much as one-fifth grain in this manner in the case of a man.

Dr. Corning and Dr. Fisher had seen cases clinically the same as the one narrated. Dr. Corning thought galvanism, supposed to be administered to the cord, had in some cases proven more than useless; it had even aggravated the condition.

Report of Committee on Legislation.—Dr. Roosa read the report. It asked the Society to continue to express its disapproval of attempts to change the present medical examiners' bill. It seemed some students of regular medical colleges were seeking its repeal in order that it might not compel them to undergo an extra examination. A hearing was to be heard on Thursday next by a Senate committee on a proposed bill affecting the Medical Examining Board, and the committee requested that twelve members be appointed to appear and defend the present law. The report and recommendations were adopted.

Mineral Waters in the Treatment of Disease.—Dr. Charles C. Ransom read the paper, describing the treatment of disease by mineral waters of Richfield Springs. It was an attempt to carefully note all the influences which might affect the case, and to analyze the benefit due to the action of the waters themselves. He hoped similar carefully kept records would soon be found in the use of waters at other springs, which would enable us to make comparisons. It was necessary in these observations to consider the influence of change of climate, environment, chemical composition of the waters, method of application, dietetic and hygienic care, etc. The author had time only to read that portion of the paper describing the waters at Richfield Springs and their manner of usual application. The chief remedial quality was sulphuretted hydrogen, and was mostly used in the form of bath, and internally.

Treatment of Endometritis.—Dr. Ralph Waldo, of New York, in this paper divided cases of endometritis, for convenience of treatment, into four classes: 1, cases in which the inflammation was confined to the mucous membrane of the cervix; 2, where confined to the mucous membrane of the body, or including that of both cervix and body; 3, the acute form; 4, the chronic. The treatment differed in the different cases, but one fact emphasized was the advantage of drainage. He objected to escharotics, as nitric acid, etc. He also condemned dilatation by tents. In chronic cases he would dilate, curette, wash out the uterus, introduce a drainage-tube (Cleveland's) or iodoform gauze.

There was considerable discussion on this paper.

Amputation of the Vaginal Portion of the Cervix Uteri in Cases of Suspected Carcinoma.—Dr. Andrew F. Currier read a paper with this title. Amputation in these cases was suggested because of the inconclusive information derived from scraping the endometrium, or even from removal of small pieces of the cervix. Of course, an early diagnosis must be made if one would have success in the surgical treatment of cervical cancer. Among conditions rendering early diagnosis difficult were, endometritis with or without hemorrhage from the interior of the uterus, hyperplasia with or without fissure of the os, or endometritis, erosions, ulcerations, and glandular disease. In many of these cases excision was not necessary to complete the diagnosis. Also stimulating and astringent applications should in some cases be tried before resorting to excision to establish the diagnosis. These applications, however, might sometimes prove injurious by increasing the rapidity of the growth and developing a malignant character. While amputation was made for diagnostic purposes, yet incidentally it sometimes cured cancer when this really existed.

Notes on Rare Cases of Skin Disease.—Dr. G. H. Fox gave pictures of several rare cases of skin disease. One was of urticarial eruption in a young man, which could be brought out by the slightest scratch on the skin. The wheals came out in about two minutes after the scratch or light blow, lasted about fifteen minutes, and caused much irritation. It lasted longer when brought out by indigestion or bodily condition. Six months' treatment had not essentially changed the peculiar susceptibility.

Another rare case was one of multiform erythema, apparently due to taking copaiba.

The third case was one of unilateral lentiginous spots which went up to the median line, but there stopped. It was the only case of pigmentation of the skin which remained unilateral.

The fourth case was one of double lumbar zoster, which disappeared after seven weeks without syphilitic treatment, proving the error of some of the New York dermatologists who had suspected syphilis.

The fifth was a case of mycosis fungoides multiplex, and the sixth one of multiple sarcoma.

Open Incision for Talipes Varo-equinus.—Dr. A. M. Phelps, of New York, presented this paper as supplementary of several which he had read on former occasions. He operated upon his first case by this method about thirteen years ago, and in spite of the absence of mortality, and the excellent results following open incision of the contracted soft parts in succession, as might be necessary, and subsequent over-correction of the talipes, surgeons continued to do osteotomy in the first instance, and also to have a considerable percentage of deaths. His method was safe, effectual, and left no sensitive scar, no flat foot, no considerable atrophy of the muscles, or other unfavorable condition, as some had seemed to fear it would. His cases were nearly two hundred.

Primary Cancer of the Liver with Biliary and Renal Calculi.—Dr. W. D. Garlock, of Little Falls, related the case. It occurred in a woman who refused operative interference for suffering attributable to a tumor at the site of the gall-bladder. Her death revealed 150

stones in the gall-bladder, and 50 in the pelvis of the kidney, also multiple nodular cancer of the liver. Cancer nowhere else was found, although examination of all the organs was not permitted. The author theorized some upon the etiological relation between the calculi and the cancer.

Pain, its Nature, Diagnosis, Significance, and Treatment.—Dr. J. Leonard Corning, of New York, read a part of his paper, reviewing our limited knowledge of the paths of pain in the cord, their passage presumably to the posterior portion of the cerebrum, and then mentioned a point in treatment. By use of a double-barrelled hypodermic syringe two fluids could be injected through the same needle before its extraction. He used oil of theobroma for deadening pain by local injection, precipitating it in the skin by means of cold, ceasing the cold when its transportation into the system was desired.

The Mental Derangements Observed in Multiple Neuritis, especially those of Alcoholic Origin.—Dr. E. D. Fischer, of New York, read the paper. The important mental symptoms were, complete loss of knowledge of commencement of the illness and of its course; while they could tell accurately events which had transpired before their illness, they lost all memory of time and place afterward. There might be the usual peripheral lesions seen in cases without special mental symptoms. He had had one case come to autopsy, that of a woman, aged thirty-six years, who gave a history of alcoholism. The brain seemed to show cell change in the cortex, especially in the pyramidal layer. The vessels were congested, and there was increase of the connective tissue. The case was of short duration, which might account for the apparently slight pathological changes. There were peripheral symptoms in this case, manifest in the arms, in the nerves of which slight changes were also found. Besides the mental symptoms mentioned there might be illusions and hallucinations.

Nasal Catarrh in Children: Importance of Early Treatment.—Dr. John O. Roe, of Rochester, read a contribution to this subject. Toward the conclusion he said, every condition of the nasal passages which produced an obstruction or caused contact between parts normally separate, manifested by a discharge, should be corrected. Any associated dyscrasia or debility of the system should also receive careful attention. Failure to give attention to catarrhal conditions in children often led to most serious consequences, relating to respiratory disorders or permanent deafness.

Fibroids of the Naso-pharynx and their Treatment by Means of the Electro-cautery.—Dr. D. H. Goodwillie, of New York, described a few of those rare cases of fibroids of the naso-pharynx which had come under his observation, and exhibited several instruments of his own device for their treatment by electro-cautery.

Evening Session.

Early High Amputation in Senile Gangrene.—Dr. C. A. Powers, of New York, read the history of one case of senile gangrene of the foot, due to arterio-sclerosis, in which he had performed amputation of the thigh in the first instance instead of below the knee, as had until recently been almost the uniform custom. His patient died of a double pneumonia, but the wound was in good condition. The object of early high amputation was to avoid the development of gangrene in the flaps. Early high amputation was first seriously considered by Jonathan Hutchinson. It had been practised in about twenty-five cases by Küster, and a number of times by other German surgeons. It should also be resorted to in gangrene due to diabetes.

The opinion was coincided in by Dr. Powers, and by Dr. Mynter and Dr. Willy Meyer, who took part in the discussion, that as long as the gangrene was confined to the toes it might not necessitate amputation of the limb. The foot should be kept elevated; when it extended to the dorsum of the foot, amputation should at once be performed about the middle of the thigh.

Note on Lacerations of the Cervix Uteri.—Dr. Graily Hewitt, of London, sent the brief paper in reply to some information asked by Dr. Chase, of Brooklyn, who read it. The symptoms following lacerations were considered largely due to disturbance of the blood and lymph circulation. When the parts became inflamed from irritation, so-called ulceration developed; with hypertrophy eversion might take place. Cicatrization with pressure upon the nerves would account for much of the pain. In regard to the influence of such injuries in the causation of cancer, he thought cancer occurred oftener in women not virgins, and still oftener in those who had lacerations. Yet he had seen none in which the cancer could indubitably be attributed to the laceration.

Nephrotomy for the Cure of Sudden Total Suppression of Urine Occurring some Time after Nephrectomy.—A paper was read under this title by Dr. Willy Meyer, of New York. The speaker said that he had so far performed extirpation of a diseased kidney six times, and that all the six patients were alive and enjoyed life. Every one of the histories presented some points of interest; but on account of lack of time he would only give one, which seemed here worthy of report. Young unmarried lady, aged twenty-eight, presented all the symptoms of biliary calculus in an enlarged gall-bladder. But laparotomy proved the tumor to be retro-peritoneal. The abdominal wound healed by primary union. Its middle, however, opened again on the twelfth day after the operation, as two silk-worm gut sutures had made pressure-necrosis on the greatest convexity of the swelling, giving exit to a large amount of flocculent pus. Nephrectomy was performed on March 19, 1891, followed by undisturbed recovery. Patient was already sitting up, passing a normal amount of urine, when, on April 26th, the thirty-ninth day after the operation, absolute sudden anuria set in. After an expectant treatment of two and a half days nephrotomy on the remaining side was done, as a mechanical obstruction of the pelvis of the kidney or ureter had been diagnosed. They were incised and found to be filled with a dense mass of coagulated pus and blood. After some work the speaker succeeded in washing out the *débris* backward, toward the pelvis of the kidney, and thus to restore the patency of the ureter. A few weeks later, at the time of menstruation, the former trouble recurred, and the whole amount of urine which had already passed the bladder again made its exit through the lumbar opening. The former hopeful condition was restored eight weeks later, after a long, worm-like shred had been expelled through the vesical mouth of the left ureter. To-day patient is perfectly cured; the wounds are healed, and a normal amount of clear urine is voided.

The main conclusions offered were: 1. Before nephrectomy, cystoscopy should, if possible, be performed to determine the presence and excreting power of the opposite kidney. 2. If sudden total suppression of urine occurs some time after nephrectomy, the cause must be a mechanical one in the pelvis of the remaining kidney, or in its ureter. Nephrotomy or ureterotomy of this remaining kidney are then the only means to save the patient's life. 3. Right after nephrectomy there is generally an acute hyperæmia of the opposite side. This hyperæmia is frequently also occurring at the time of menstruation, but probably to a far less degree. 4. This hyperæmia often suddenly increases a disease of the remaining kidney, hitherto symptomless. It may also bring to perforation into the pelvis of the kidney an abscess, so far encapsulated in one of the pyramids.

Two Successful Cases of Conservative Cæsarean Section—Dr. Charles Jewett, of Brooklyn, read the history of the cases, both of which he operated upon in a hospital during December. The narrowing of the pelvis was due in each case to previous disease of the vertebræ. It

was intended in the first instance to perform craniotomy, but, the woman being a Catholic, Cæsarean section was performed with a successful result. Labor had begun. The child lived. In the second case the narrowing was greater, abortion had begun, section was performed according to the Saenger or improved method. He employed in each provisional ligation of the cervix by a soft hollow rubber tube. As far as possible entrance of blood and amniotic fluid into the peritoneal cavity was prevented, yet it should not be necessary, if proper aseptic precautions were taken, to wash or sponge out the cavity. Such interference was in itself objectionable.

The Operative Procedures in Uterine Displacements.—Dr. O. E. Herrick, of Grand Rapids, Mich., read the paper, describing a method which he had practised over twelve years in posterior displacements without adhesions and complications. Its object was to shorten the utero-sacral ligaments, thereby pulling the cervix back, which threw the body forward. The method had been more recently employed by Saenger without reference to the author's work. He regarded the method as more rational than that of shortening the round ligaments and ventral fixation. His results had been uniformly successful. He preferred silver wire as suture. Denudation was made, and the suture introduced by means of the curved needle, passing through the posterior surface of the cervix, high up through the walls of the cul-de-sac, close to the uterus, back close to the rectum, again into the vagina. The result was to cause the utero-sacral ligament to become folded upon itself, shortened, the uterus drawn up, the body forward.

Dr. Edebohls spoke strongly in favor of shortening the round ligaments, although he thought the author's method might have a place in some cases.

A Case of Extra-Uterine Pregnancy, Death of Fœtus at Third Month, and Fatal Hemorrhage Outside the Sac at Fourth Month.—Dr. I. S. Stone, of Washington, read the notes of the case. The autopsy revealed the conditions described in the title, death having taken place soon after the patient was brought in, following hemorrhage.

Second Day, Wednesday, February 3d.

The Crossed Suture.—Dr. George R. Fowler, of Brooklyn, sent the paper, which was read by Dr. Delatour. It consisted essentially of a suture which separately united the different layers of the walls of the wound by crossed suture from below upward, from the deeper portion to the integumentary surface. It was specially useful in laparotomy cases and herniotomy.

Notes on the Operative Treatment of Urethral Strictures.—Dr. F. R. Sturgis, of New York, stated, in the concluding remarks of a paper upon this subject, that no operation on the urethra, not even the simple introduction of the sound, was entirely devoid of danger. Perineal section was safest; next in comparative safety was gradual dilatation; next rapid divulsion; then came internal urethrotomy; electrolysis had not realized its promises. Caustics had been abandoned, but might be applicable since the introduction of the endoscope. He would in a given case first try gradual dilatation; if this failed, ordinarily he would try rapid dilatation, at least where the stricture was four inches from the meatus; perineal section, if deeper; internal urethrotomy, if less than three inches.

Compound Fractures and Their Treatment.—Dr. Herman Mynter, of Buffalo, read the paper. He described Volkman's greatly improved mortality rate when, instead of following the old method of sealing the wound in the skin, he explored it, removed foreign substances, pieces of bone, washed out, and drained. Under former prevailing methods the mortality in compound fractures, of the thigh, for instance, had been from thirty-eight to fifty per cent. and higher. Volkman published his method fifteen years ago, yet text-books had not yet fully thrown off old methods.

Dr. Mynter had for some years resorted to a more radical procedure than Volkman's. He always explored the wound, removed broken pieces, bruised tissues, cut off sharp edges, opened up pockets, turned out clots, cleansed. He preferred to do too much rather than too little. Thorough cleanliness was established. Drainage-tube was not inserted. Light plaster-of-Paris dressing was put on, and not removed without indication.

In the same hospital where his predecessor had sixteen successive deaths, he had as many successive recoveries. He gave statistics of eleven cases of compound fracture of the thigh, with successful results in all except one, which terminated fatally from delirium tremens. No pus had formed in any.

Abolition of the Death Penalty.—Dr. A. Jacobi read the report of the special committee appointed last year to consider the advisability of recommending to the Legislature the abolition of the death penalty. The committee consisted of Drs. Jacobi, William Wey, and B. F. Sherman. The report considered the subject from the point of view of science, going in considerable detail into the conditions influencing the abnormal development of the brain and abnormal or perverted mental action.

Back of many crimes was a history of some of the following conditions: protracted labor, faulty use of forceps, asphyxia, rachitis, hydrocephalus, epilepsy, idiocy, syphilis, alcoholism, the dime novel, masturbation, etc. Many persons had suffered the death penalty who were mentally irresponsible owing to disease. Many suicides were the result of cerebral or mental disease. Owing to the difficulty of recognizing such abnormal mental or cerebral conditions, and of convincing a jury of their existence, and for other reasons, the committee favored the abolition of the death penalty.

On motion the committee was continued another year, the report ordered published in the Transactions, and a thousand extra copies printed for general distribution by the committee.

Intravenous Saline Infusion for the Relief of Shock in Acute Anæmia.—Dr. L. S. Pilcher, of Brooklyn, read the paper. The merit of novelty, he said, no longer attached to this method. The extent of usefulness of the method and its technique had not been sufficiently appreciated. The cases in which it was applicable might be divided into three classes: 1, Those in which the element of hemorrhage predominated; 2, those in which shock and hemorrhage were both present in marked degree; 3, those in which shock predominated. The object was to restore blood-pressure. Heretofore too little fluid had been injected, which accounted for only temporary instead of permanent reaction. It should be repeated if the symptoms returned. The procedure was simple, and capable of being applied by any physician.

Surgical Shock.—Dr. J. H. Packard, of Philadelphia, read the paper, which discussed the subject in a comprehensive manner. He distinguished between shock and collapse. It was desirable that more accurate observations and records should be made of the early phenomena in shock. Especially should the temperature be taken. The skin was cold, but was the temperature always so? The author had seen reduction of temperature usually when taken. It had fallen in two cases on record below 82° F. It should give some indication as to the necessity for heroic measures.

He spoke of points in prevention in surgical shock—obviate prolonged narcosis, do not expose patient to cold or to unnecessary wetting during operation, etc. If before undertaking the operation the pulse flagged and became irregular under ether, abstain from operating. As to treatment, it had consisted in application of heat, stimulants by hypodermic injection, driving blood centrally, etc. He had not used injections of nitro-glycerine.

Those who discussed the paper favored larger hypodermic doses of strychnine and other stimulants.

Discussion on the Surgical Management of Genito-urinary Calculus.—Papers relating to special phases of this subject were read by Dr. J. D. Bryant, on "Diagnosis and Indications for Surgical Treatment;" by Dr. L. A. Stimson, on "The Surgical Treatment of Stone in the Kidney;" by Dr. A. T. Cabot, of Boston, on "Stone in the Ureter;" by Dr. E. L. Keyes and Dr. L. B. Bangs, on "Stone in the Bladder, what Special Indications should Govern a Choice of Operations as between Lithotomy and Lithotrity."

Fibroid Diseases of the Heart.—Dr. A. L. Loomis read a paper on this subject. He described the changes found in two illustrative cases, both of the patients having suffered from præcordial distress and died suddenly. The fibroid change was present in the left ventricle in plates replacing the heart-muscle in parts, in other parts the fibroid changes had replaced certain muscle-fibres, and other fibres were about to undergo a similar change. There was fibroid change in arteries also, especially of branches of the coronary artery. There was no evidence of the fibroid change being secondary to inflammation in the endocardium or pericardium. The kidneys were typical in these two cases of the early stage of renal fibrosis.

When he began investigating the subject he entertained the common opinion that a diagnosis could not be made during life; that the clinical picture was that of valvular disease when compensation ceased. He now believed the diagnosis could be made, based on the loss of cardiac rhythm, which came early, never entirely disappeared, and could not be restored by cardiac tonics. Digitalis and other like stimulants did no good, but were likely to do harm. The cause was defective nutrition, through toxic blood, toxic influence on cardiac nerves, change in the arterioles of the coronary artery, which seemed to be always present, and trauma. Preventive treatment consisted in milk and vegetable diet, promoting oxidation by free air and exercise, remove nitrogenous waste, etc.

The Importance of Drainage in the Treatment of Diseases of the Endometrium.—Dr. W. Gill Wylie in this paper described the method he had taught and practised for thirteen or even twenty years in the treatment of diseases of the endometrium. In cases without subinvolution or tumor it was necessary to forcibly dilate, then curette, wash, drain, perhaps apply tincture of iodine or carbolic acid. The best drain was the hard rubber, grooved stem, with a slight bulb, and proper curve. Gauze was not practicable in these cases.

A long discussion followed, in which Dr. Polk and others upheld the use of gauze, while Drs. Mordecai and Joseph Price and Hoffman, of Philadelphia, claimed there was no inflammation of the endometrium except gonorrhœal which called for treatment, and claimed that dilatation and applications were a most frequent cause of pyosalpinx, etc.

Drs. Mundé, Dudley, Boldt, and others upheld the necessity for treating endometritis, although admitting that methods may have been abused.

Ectopic Gestation, Its Comparative Symptomatology and Treatment.—Dr. Joseph Hoffman, of Philadelphia, read this paper. The diagnosis depended very largely on the symptomatology. It could seldom be made before rupture, because the symptoms were not such as to drive the patient to the physician. He urged immediate operation, when, as was the rule, symptoms of rupture had taken place. Do not in any case dally with electricity, opium injection, etc.

Vaginal Hysterectomy for Cancer.—Dr. E. W. Cushing, of Boston, in this paper argued in favor of total extirpation in cancer of the uterus, stated that he had usually employed clamps instead of ligature, had operated in about thirty cases—fifteen of the patients were yet living—without recurrence. Whenever, in his case, recurrence took place, it was always within six months of the operation.

Dr. Boldt upheld total extirpation as opposed to high amputation. Like views were expressed by Dr. Joseph Price.

Drainage in Abdominal Work.—Dr. Mordecai Price, of Philadelphia, read this paper, expressing in a most positive manner the opinion that in the practice of his brother, Dr. Joseph Price, and his own, the excellent results were in a large measure due to drainage. They had employed drainage in over one thousand cases of laparotomy with a mortality, excluding no cases, of not more than one to three per cent. Every form of intraperitoneal disease, liver abscesses, abscess of the spleen, disease calling for nephrectomy, etc., was included. They used the glass drainage-tube, unless they wished to set up adhesive inflammation, as around a liver abscess, when they employed gauze. The author, Dr. Joseph Price, and Dr. Hoffman, of Philadelphia, took firm ground in their preference for the glass tube as opposed to gauze-packing in most abdominal work, while Drs. Dudley, Boldt, and others asserted in an equally positive manner that gauze was generally far preferable to the glass tube.

Recommended for State Medical Examiners.—The special committee, consisting of Drs. Roosa, Daniel Lewis, Charles Jewett, Charles Stover, and Clark (of Buffalo), recommended in their report the following gentlemen for State Medical Examiners: Drs. Eugene Beach, of Gloversville; Creveling, of Auburn; B. F. Sherman, of Ogdensburg; A. Walter Suiter, of Herkimer.

The report was adopted and these gentlemen recommended to the Board of Regents, from whom to choose two as Medical Examiners.

The President's Address.—The evening session of Wednesday was held in the Senate Chamber at the Capitol. Dr. A. Walter Suiter proceeded to read his address, which related to public hygiene. In it he reviewed the form in which health boards had existed in ancient and modern times, and made special mention of the interest in matters of public health shown by European governments. The course adopted by Germany was nearly ideal. He showed the advantages to be gained by our country in establishing a national health board in some form, whether it were called a department, a bureau, or a board. There should be one responsible head, able assistants, to be undisturbed by political changes, with ample funds for prevention of disease, making original investigation, etc. At present it would seem there should be two national boards under one head, one relating to public health in the interior, the other, like that of the Marine Hospital Service, to prevent importation of disease.

A vote of thanks was extended the President for his able and instructive address.

Report of Nominating Committee.—For *President*, Dr. Lewis S. Pilcher, of Brooklyn; *Vice-President*, Dr. H. L. Elsner, of Syracuse; *Secretary*, Dr. F. C. Curtis, of Albany; *Treasurer*, Dr. C. H. Porter, of Albany; *Committee on Legislation*, Drs. Roosa, Daniel Lewis, and M. J. Lewi; *Committee on Prize Essays*, Drs. G. H. Fox, W. W. Potter, and J. O. Roe.

Expulsion of a Tape-worm by the Mouth.—Drs. Bernard and Renaud have reported (*Journal des Sciences Médicales de Lille*, No. 18, 1891) the case of a young woman who suffered from repeated attacks of weakness and syncope followed by copious emesis. During one of the attacks of vomiting she delivered herself of a perfect tape-worm about ten feet in length, soon after which all her troubles ceased.

Glottic Spasm.—Sir Morell Mackenzie says that a little snuff or other nasal irritation, sufficient to excite a paroxysm of sneezing in the infant, will cut short an attack of spasm of the glottis.

Correspondence.

OUR LONDON LETTER.

From Our Special Correspondent.

INFLUENZA—INCREASE IN THE NUMBER OF DEATHS—THE FATAL ILLNESS OF THE DUKE OF CLARENCE—ROYALTY AND THEIR MEDICAL ATTENDANTS—DR. BROADBENT—GOUT OF THE PENIS—TREPHINING FOR HEMORRHAGE FROM THE MIDDLE MENINGEAL—CEREBRAL HEMORRHAGE—GALVANO-CAUTERY FOR PROSTATIC OBSTRUCTION.

London, January 16, 1892.

"Influenza" is the one subject at present to the front, and one of overwhelming interest to both the profession and the public. The epidemic shows as yet no signs of abatement in the metropolis—or, indeed, in any part of the United Kingdom, except Scotland and some parts of Wales. In the week ending January 9th the deaths registered in London as due to influenza were ninety-five in number, or nearly three times as many as those registered in the previous week. (The returns for the present week will probably show an even larger mortality from the disease.) Doctors are being summoned in all directions at once to attend on influenza patients, and I understand that two medical men in partnership in the West End attended between them no fewer than eighty cases in one day. Public excitement was intensified by the news that the Duke of Clarence and Avondale was prostrated with the disorder, and especially when it became known on Wednesday that his condition was critical. The intelligence of his Royal Highness's death on Thursday morning reached London about ten o'clock and the public excitement then attained its highest point, almost equalling that which was evinced twenty years ago when the Prince of Wales lay ill with typhoid fever. Long before these lines are read by your readers, however, all details of the case will have reached them by cable, so I do not propose to take up your space by relating what is already known to them. A few lines on some other aspects of the case may, nevertheless, be of some interest. In the case of a royal patient, the ordinary medical attendant is, in general, first summoned. For the Queen, this would be her resident physician—Dr. Reid—who is always in attendance on Her Majesty and travels with her wherever she goes. The Prince of Wales has no resident medical attendant, but, in London, the Surgeon-Apothecary to the household—Dr. Laking—is close at hand, as he practises in Pall Mall, just opposite the gates of Marlborough House, and at Sandringham, Dr. Manby, the Surgeon-Apothecary to the Prince and Princess of Wales there—resides within a short distance; neither Dr. Laking nor Dr. Manby, however, are exclusively retained for their royal patients but are both in the enjoyment of large and lucrative practices in their respective localities. Supposing a Royal personage to be attacked by a grave malady, one of the physicians or surgeons in ordinary would next be summoned. This course has, though, not been invariably pursued, and was notably departed from in the case of the Prince of Wales's own serious illness, when Sir William Gull (then plain Dr. Gull) was called in and the Prince of Wales's own Physician-in-Ordinary not sent for.

In the recent illness of Prince George of Wales the precedent thus created was followed. Dr. Manby saw the young prince, and after his removal to London, Dr. Laking. Then, however, Dr. Broadbent was called in and not one of the Prince of Wales's own Physicians-in-Ordinary. Prince George of Wales had, however, no officially appointed medical attendant, and in his case, therefore, the calling in of a physician not already holding a Court appointment did not excite as much comment as was caused by the action with regard to Dr. Gull, in the Prince of Wales's own case. The selection of Dr. Broadbent to attend Prince George was doubtless prompted by the desire to obtain the services of a physician with special experience of the fever which has proved so dangerous to the royal family. Dr. Broadbent was for many years physician to the London Fever Hospital, and is the author of the elaborate article on "Typhoid Fever" in "Quain's Dictionary of Medicine." Dr. Broadbent is one of the few medical men receiving their medical education in the provinces who have attained high professional rank in London. Studying at the Manchester School of Medicine, he graduated at the University of London with high honors, obtaining an exhibition, a scholarship, and four gold medals. He then came to London to fill a minor appointment at St. Mary's Hospital—that of resident obstetric officer. A vacancy for an assistant physician occurring shortly afterward he applied for it, and his work had already produced such an impression that he was elected. This was about thirty years ago and Dr. Broadbent's name has been associated with St. Mary's Hospital ever since. He is at present the senior physician and was elected last year for an additional five years as physician to the hospital, although he had completed the twenty years' service as in-patient physician allowed by the rules. Early in his London career he obtained a reputation for thoroughness in his work. He was unremitting in performing his hospital duties in the out patient department, and would spend many hours in elucidating obscure cases and demonstrating them to the students. The physiology and pathology of the nervous system early attracted his special attention and he published several papers embodying original researches and theories in neurology. His theory of the association of certain nerve nuclei on opposite sides of the body—which explains certain anomalies observed in both paralyses and convulsions—was described in a paper published in the now defunct *British and Foreign Medico-Chirurgical Review*, in 1866, and speedily obtained general recognition. Since then Dr. Broadbent has published numerous papers on various subjects but he is the author of only one medical work, viz., "The Pulse," a volume published a few years ago. He speedily produced the impression on his pupils, his colleagues, and his patients of "a man who knew," and was not long in laying the foundation of a large private practice, now larger than that of any other London physician. Dr. Broadbent's success has not been gained by any special charm of manner, nor by any peculiar "gift of the gab," to which it is said the success of one very fashionable physician is due. As, however, his hospital pupils found that he was a very careful and accurate observer of physical signs and symptoms, and one skilful to interpret them aright, so did his private patients learn to repose confidence in his opinion, and believe that it was based on a thorough knowledge of disease. In his practice he has ever been ready to adopt new methods of treatment when desirable, and, on the other hand, has been equally willing to revert to old and tried remedies in preference to "new fangled" ones when they have commended themselves to his judgment. Few of his students but will remember how strenuously he has urged the value of bleeding in certain cases, and of how he has insisted on the benefit often obtained in chronic—even non-syphilitic—cases by the administration of small doses of mercury. Having gained the confidence of the royal family in the case of Prince George of Wales, it is not surprising that he should have been summoned to Sandringham to attend Prince Albert Victor, but, unfortunately, with a less favorable result than in the case of the younger prince.

At the last meeting of the Clinical Society Sir Dyce Duckworth gave an account of a case of gout of the penis. There was painful priapism, persisting without intermission for twenty-one days; it then gradually subsided with general amendment of all the symptoms. Dr. Ord remarked that he had never met with the condition in an acute form. Mr. Bland Sutton read notes of a case of fracture of the skull complicated with hemorrhage from the middle meningeal artery in which trephining was per-

formed, the artery secured, and a successful result obtained.

At the Medical Society on Monday evening, Dr. Churton read the notes of a case of cerebral hemorrhage, presenting some features of interest. There were signs of both femoral (right) and pulmonary phlebitis; there was also complete anæsthesia of the left foot. It was found after death that there had been hemorrhage almost simultaneously in both hemispheres. Mr Bruce Clark read a paper on "The Radical Cure of Prostatic Obstruction by the Galvano-cautery."

THE USE OF WOMAN PHYSICIANS.

To the Editor of the Medical Record.

Sir: A series of open letters in the *Century Magazine*, some months ago, concerning the woman doctor, contained much matter and some pith. The wise things said by Josephine Lowell, the outcome of intelligent experience, are worthy to be incorporated into whatever creed the public may hold henceforth in regard to medical women.

Inherent womanliness, says Mrs. Lowell, constitutes the chief characteristic of the ideal woman physician. It is upon the womanliness of educated women that is based the strongest argument in favor of placing under their care women who are suffering from disease, either physical or mental, and women who have lost all womanliness. To the strong, to the well, to the good, to the happy, sympathy is not essential. They can live without it. To the weak, the suffering, the crushed, and the wicked sympathy is the first necessity. They must have it, or they cannot be lifted and cured. Now the sympathy that one woman can give to another is impossible from a man. The common sympathy that one human being may feel for another under all circumstances will in such event be perverted by an abnormal mind, and work harm instead of good. To women shut away in insane asylums, prisons, and reformatories, for their own care and the safety of others, the ministrations of high minded womanly women are almost a necessity. To have men in exclusive charge of such cases is to throw away the strongest influence for good which can possibly be available for the reformation and cure of either prisoners or patients. A woman can know a woman as a man cannot. And a young, ignorant, wayward girl, will often conceive for a calm browed, steady minded woman physician an extent of devotion that will serve to keep her from wrong through life. No man can stand in such a relation to the girl.

In the same series of open letters appears one from Dr. Charles Folsom, of Boston, in which he says: "The community needs a woman's educational view of morality, rectifying and revising standards. And therein, perhaps, is one opportunity of many for the woman physician of the future to help. By bringing the work of the best women into the practice of medicine the medical profession must be benefited and the world may be improved."

Earnest women of well trained minds have an instinct for reform. They unearth the forgotten things, and give time and attention to details that men have not the inclination —perhaps not the ability—to undertake in serious part. And no one denies the importance of such endeavor, which is as essential to progress as the creative faculty. Rational dress, simpler methods of domestic life, educational reforms, and the wise protection of childhood, are, in a measure, the result of intelligent efforts on the part of woman physicians. The use of medical women may be quite outside the department of discovery, analysis, or invention. But even the casual observer will admit that the sensible, womanly woman, trained in the medical sciences, is to-day a power for good indispensable to the better life of this world. That things are not so bad as they might be for womankind at large is the result of silent, obscure effort, to heroism that never sees the light of day, to the applied intelligence of educated women, earnest purpose, especially the intelligence of the medical remnant.

A Woman Physician.

THE ANTISEPTIC TREATMENT OF TETANUS.

To the Editor of the Medical Record.

Sir: In an article on "Tetanus" by Dr. Licorish, of Barbadoes, published in the Medical Record of July 28, 1891, the author regards the disease as one of the sympathetic. Its first symptom is not, he says, stiffness of the muscles of the neck and jaws, but a pain or indescribable sensation in the epigastric or umbilical region, due, he believes, to an affection of the abdominal sympathetic ganglia. His treatment consists in the administration of purgatives, especially salines, and nervous sedatives, preferably belladonna. One of his colleagues, who uses the same method, giving a dose of calomel at the commencement, says that he has ceased to regard the disease as one of such a desperate character since beginning this mode of treatment. As to the theory of infection, the author thinks it probable that the microbe of the disease resides always in the organism, and is called into activity only in consequence of a wound or the action of cold. That is the substance of the abstract of the article which I saw in the *Anales de la Asistencia Pública*, of Buenos Ayres (being prevented from reading it in the original by my inability to read English), and my remarks are based on the assumed correctness of this abstract.

I do not think that the author of this communication can be unaware of recent investigations into the nature of tetanus, which would show it to be of equine origin. M. Vernenil and others have found the bacillus of tetanus in stables, manure heaps, pastures, and in the ditches in which the bodies of horses have been buried. The bacillus is found at a certain depth in the earth, and also in the dust of places in which patients were first cared for when wounded. When the results of these investigations were communicated to the Académie de Médecine, the friends of tradition did not fail to show their conservatism, and maintain that there might also be a *tetanus a frigore* as well as a bacillary one. For myself it is theoretically impossible and contrary to reason that two different agents should produce identical effects. Either there must have been an error in diagnosis in the case of the supposed *tetanus a frigore*, or else it was true tetanus, due to the invasion of the bacillus, which bacillus, however, the observer has not looked for or has not known how to recognize.

I admit that the identity between two diseases, of which one follows traumatism and the other presents no apparent point of entry for the microbe, might be held to corroborate the conjecture of Dr. Licorish that the bacillus is constantly present in the body, but there are so many arguments to be raised against this hypothesis, ingenious as it is, that it cannot be maintained. The first objection is drawn from the relative rarity of tetanus as compared to the frequency of the causes—traumatism and cold—which may produce it. I know that this malady is much more common in certain warm countries than it is in Europe, but the endemic character which it assumes in these countries may be explained, it seems to me, in the same way as that of cholera in India, or yellow fever in America, endemics the first causes of which are not to be found within the organism itself. The tetanic bacillus becomes more diffused in proportion to the number of persons it attacks and destroys.

As to the treatment advised by the author, it may be excellent, but if so it is solely because it is antiseptic, or, according to the barbarous term in common use, microbicidal. Calomel is a powerful antiseptic, and belladonna is a nervine, the effect of which may be to para-

lyze the vital and reproductive powers of the bacillus. In the *Wiener Medizinische Presse*, No. 7, 1890, a case is related of a boy, fifteen years of age, suffering from tetanus following a contused wound, for whose relief all the ordinary remedies, warm baths, chloral, etc., had been tried without any effect upon the temperature or the muscular rigidity. Dr. F. Paolini then, four days after the receipt of the accident, had recourse to hypodermic injections of a one per cent. solution of phenic acid, repeated every three hours for four days. From the first day the temperature began to fall and the trismus and muscular rigidity to diminish, and the result was a complete cure. Another patient was treated by Dr. Baccelli for tetanus in the same way, with the same result, and medical literature contains still other cases of the same kind.

It is my firm conviction that phenic acid, employed in the manner indicated in my "Manual of Antiseptic Medication," recently reviewed in your columns, will not only relieve pronounced cases of tetanus, but will also be found a prophylactic when used in the treatment of wounds. It is not only an efficacious remedy in case of the invasion of the bacillus, but is also the most efficient barrier which can be raised against its diffusion and propagation.

If you will kindly present these views to your readers, I shall esteem myself happy in having rendered them the service through this channel. DR. DÉCLAT.

VILLA DÉCLAT, QUAI DU MIDI, NICE, December 25, 1891.

FAVORITISM AT THE NEW YORK ACADEMY OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It has seemed to me that the letter recently published in your columns by Dr. Amidon, although unnecessarily petulant and disagreeable in tone, contained two remarks deserving of further consideration. The first was to the effect that, as non-members of the Academy now enjoyed its principal advantages without having to pay for them—notably the privilege of its library, the freedom of its beautiful building, and the right to attend its meetings—there was little inducement to become a member, especially since the membership dues had been so much increased.

One would imagine that a New York physician of many years' standing, would consider it a point of honor to share in the expense of securing advantages so necessary to the entire profession, and so liberally thrown open to all. Who that can possibly help it wants someone else to do his paying for him, without offering a return? Who feels proud of the privileges of a deadhead? If I entirely condemn this first remark of Dr. Amidon's, I must, however, entirely second his protest against the present system of managing the stated meetings and debates at the Academy. The very purpose of the system introduced by the late president, Dr. Jacobi, to enlarge the membership of the Academy as much as possible, instead of keeping it as restricted as possible, was to secure a constant infusion of new and young blood, to avoid the tendency to stagnation and fossilization which had hitherto prevailed. This purpose is defeated by the present habit of restricting debate to a limited number of speakers, always the same in each given range of subjects, well known to habitual and patient attendants at the meetings, and extremely liable to repeat their own views, which are also well known, over and over again. It is certainly a great improvement on former practice, that one or two persons should be invited beforehand to discuss the paper of the evening. But when no space or opportunity is left for extemporaneous debate, the chief zest of the occasion is missed, for nothing is struck off on the spur of the moment, and while the mental iron is hot. Those who come to the debate prepared beforehand, very rarely speak upon the paper, even when they really contribute something further to the discussion of the subject; and if debaters must be invited beforehand, why should not the rolls of the Academy be examined more impartially and systematically, so that continually new members should be invited to debate? It is the newer and younger members who might more especially be supposed to require previous preparation; those who are thoroughly conversant with a subject, might be expected to be able to talk about it at the moment it comes under discussion, be able to have ideas suggested by what the speaker says, and not be compelled to conceal their inability to follow the speaker, by a discourse on points quite other than those he has raised.

The reason of existence of the Academy of Medicine, is to furnish incessant mental stimulus to the medical profession, where intellectual interests are constantly liable to be forgotten amid the drudgery of daily work. For this purpose every effort should be made to diffuse such stimulus, and to incite members to work, instead of coaxing them to come and sit in an audience by bribes of chicken-salad and ice cream.

ANOTHER FELLOW.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with interest and approval the letters recently published in your columns relating to the management of the Academy of Medicine of this city. They no doubt reflect the sentiments of a large majority of the members having the true interests of that institution at heart. It is well to keep up the attack thus worthily opened, and therefore I ask to call attention to another point in connection with the Academy which would seem deserving of criticism and to call for agitation. This refers to a growing tendency observable to convert the Academy at the annual elections into a political machine to be used to further the interests of certain medical colleges by securing as many of the offices as possible to its faculties and friends, as has been openly practised for several years in the politics of the County Medical Society. Openly or secretly electioneering to this end deserves to be frowned upon by everyone who respects the Academy, and we should see to it that all candidates thus put forward are promptly "snowed under" at the voting.

Put to such unworthy purpose, the Academy must surely soon cease to serve its proper function, and its most worthy members will cease to take much interest in its proceedings, diverted from disinterested scientific pursuits.

It would seem highly desirable that members should put aside private and irrelevant interests on entering its jurisdictions, and aspire with unanimity to make the Academy the representative scientific medical society of the country, as it ought to be, but as it surely cannot be without this. Respectfully,

A NEW MEMBER.

NEW YORK, January 23, 1892.

THE TREATMENT OF HEMORRHAGE BY THE INFUSION OF SALINE SOLUTIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD, vol. xli., No. 1., appeared an article by Dr. R. H. M. Dawbarn on the surgical treatment of medical hemorrhage, in the course of which is advocated the infusion of a 0.6 per cent. saline solution at or above the temperature of the blood. Dr. Dawbarn also cites an interesting case in which the value of this measure has been successfully demonstrated. This mode of treatment is not new, because experiments and cases have been reported since 1879.

Schwarz[1] has made a number of experiments on rabbits and dogs, in which he demonstrated the high value of intra-venous and intra arterial infusions of a 0.6 per cent.

[1] Centralblatt für Gynäcologie, 1881, and Berlin. Klinische Wochenschrift, 1882.

saline solution. The animals recovered permanently after the abstraction of immense quantities of blood.

Kronecker and Sauder,[1] also Ott,[2] report equal good results. The experiments of Ott have been very minute, and were made under the supervision of Cohnheim.

Kümmel[3] publishes two cases from Schede's clinic in Hamburg, in both of which intra-arterial infusion had been applied. The apparatus he used was a glass funnel, rubber tubing, and a large hypodermatic needle.

Case I.—Male, aged twenty eight, much run down. Nephrectomy was pertormed for hydro nephrosis. Marked collapse from loss of blood. Pulse small, 132. Respiration, 40. Infusion into the radial artery of solution of NaCl 0.6 per cent., 1,000 grams, at 40° C. Improvement followed, and finally all symptoms of collapse disappeared. The patient died the second day from amyloid degeneration of the other kidney.

Case II.—Female, aged sixty-one. Resection of knee-joint for suppurative arthritis. The day following the operation severe secondary hemorrhage, symptoms of extreme exsanguination. Infusion of 500 grams into the ulnar artery, rapid improvement of symptoms. Two days later the arm in which the infusion was made became gangrenous and had to be amputated. The gangrene was caused by thrombosis of the ulnar artery and its branches.

Bishop[4] reports the following case.

I-para, aged thirty one, severe post partum hemorrhage; 1,450 grams of blood were collected in one vessel. Collapse. Pulse, 156, only at times perceptible. Extremities cool, death seemed imminent. Infusion of 1,250 grams into the radial artery was followed by a rapid subsiding of all the bad symptoms. Recovery.

Küstner publishes one case out of Schulze's clinic in Jena. Laparotomy was performed for carcinoma of the peritoneum. The woman was in a very poor condition, and the loss of blood brought on collapse. Infusion of 1,000 grams caused some improvement. The method employed by these men does not differ much from that of Dr. Dawbarn, the radial or ulnar arteries are substituted for the femoral artery. The apparatus used is practically a fountain syringe, and this has the advantage over the Davidson syringe, that with a little care the introduction of air is an impossibility. I also wish to remark that the Davidson syringes found in private houses have served various purposes, and are not in a very aseptic condition. The second case of Kümmel teaches us to bear in mind the danger of thrombosis.

Dr. Dawbarn refers to the method employed in the lying in hospital in Dresden. Dr. Münchmeier, at that time first assistant, has published an exhaustive paper on this subject.[5] He also reports eight successful cases, while in ten others no improvement followed. The infusion is made subcutaneous instead of intra-vascular. The apparatus and solutions are the same as previously described. While I was assistant in Dresden, two cases of collapse following hemorrhage from placenta prævia were treated by this method. I will briefly report them.

Case I.—VI-para, aged thirty-six, normal pelvis; very anæmic. Had suffered for some weeks from uterine hemorrhages.

Diagnosis.—Placenta prævia lateralis, vortex presentation, os nearly dilated, membranes intact, moderate hemorrhage. Podalic version was done under chloroform; during the operation pulse small and rapid. A living child was extracted, and this was followed by considerable hemorrhage from a lacerated cervix. The hemorrhage was immediately arrested, but the woman was so anæmic that this hemorrhage proved fatal. Infusion and enemata of saline solutions, also the free use of analeptics, were unable to combat the collapse, and she died one and a half hour post partum.

Case II.—IX-para, aged forty-three, very deplorable condition, cold and pulseless; history of severe uterine hemorrhage was given.

Diagnosis.—Normal pelvis, vortex presentation, os dilated, membranes intact. The membranes were ruptured, no further hemorrhage, and the case was left to nature. Fifteen minutes later, birth of a dead fœtus. Subcutaneous infusion was successful in this case, she rapidly improved, and left the clinic on the tenth day.

VIS PROTECTRIX NATURÆ IN THE VEGETABLE WORLD, AND ITS RELATION TO THERAPY IN THE ANIMAL WORLD.

To the Editor of the Medical Record.

Sir: Your editorial of December 19, 1891, entitled "The Discovery of the Vis Medicatrix Naturæ," suggests that the same principle therein discussed in relation to animal life doubtless is applicable, also, to vegetable life, and that herein may perhaps be found the key to the therapeutical application of certain vegetable drugs. We know that the balsamic products, for example, have protective functions in the economy of those plants which secrete them, and that from them are derived some of our best germicidal agents, as well as other potent medicines. May not the vegetable alkaloids, and many other vegetable medicines, hold the same relation to the lives of the several plant species which produce them?

Maclagan, I believe, in discussing salicin as a remedy in acute rheumatism touches upon this, but he regards it as the result of providential design for man's benefit, arguing that wherever any human disease is prevalent there will be found its remedy, providentially prepared by indigenous vegetation. I should say that nearly everything in the world might be rationally regarded as, in a sense, providentially designed for man's use, but that, at the same time, particular applications must be diligently sought out and wisely made before the design becomes apparent. This is only to say that all nature (man included) is comprehended under one universal bond of connection and of interdependence, and that man, as the head and the possible comprehender of it all, must have the latent (at least) capacity for all its uses. But it does not necessarily imply that any particular thing was originally designed for him as distinctively man, but rather he is the distinctive and inevitable product of everything else in nature, and consequently, by reflex, in sympathy with everything. The following seems to me the better explanation of how salicin happens to be found where it is needed as a remedy for rheumatism.

The willow's natural home is in the cold and damp soil where the germs of rheumatism are supposed to lurk. In the evolution of the willow species, we may suppose that it had to fight for existence against the germ (or a similar one) that now produces rheumatism in the human species. It survived the struggle by virtue of salicin, which a yearning want evoked from its chemical elements, as a necessity of its continued existence. Salicin having at length become a natural ingredient of the willow, the latter was thereafter secure from the foe which had formerly most especially threatened its life. It is not essential to the argument that this application of salicin to rheumatism should fit, but as a matter of fact I believe it is a very good fit, having used salicin for nearly ten years in every case of acute rheumatism occurring in my practice, and never once having seen it alone fail to control the symptoms within a week. If it fail, it will be from too timid dosing.

The analogy between vegetable alkaloids and ptomaïnes perhaps indicates that they play similar parts in their respective spheres.

There is no apparent proof that plants, during their evolution as species, were subject to attacks by the same microscopic foes as are now wont to infest human flesh,

but it does not seem very improbable; and, therefore, we may have but to listen with sufficient attention to learn the secret source of the remedy for every infectious disease hidden somewhere in the vegetable kingdom.

This theory of plants having acquired immunity from diseases to which they were by supposition formerly subject, may afford an explanation of how an individual of the human species gains immunity from subsequent attacks of an infectious disease, like scarlet fever, by having suffered one attack. The conclusion would be that, by infinite repetition of the disease among individuals, immunity would finally become a permanent accumulation in the species. The individuals would be born protected.

In the meantime there is ample scope for usefulness in the medical profession, in discovering and skilfully transferring to afflicted individuals of the human species the remedies for diseases accumulated and stored up by other older species.

Doubtless, to many readers all this will appear fanciful, and it is offered only as suggestive of possibilities, grasping after unattainables, perhaps—a poetic aspiration, as it were, of materia medica.

Respectfully yours,

HOBART CHEESMAN, M.D.

328 WEST FIFTY-SEVENTH STREET.

Clinical Department.

TWO CASES OF STRICTURE OF THE URETHRA, WITH INTERESTING FEATURES.

BY JOSEPH L. BAUER, M.D.,

ST. LOUIS, MO.

PROFESSOR OF GENITO-URINARY SURGERY; ASSISTANT PROFESSOR OF ORTHOPEDIC SURGERY, ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS; SURGEON TO ST. MARGARET'S HOSPITAL FOR WOMEN.

CASE I. *Close Stricture of Membranous Urethra—Retention of Urine—Septic Poisoning—Ultimate Recovery.*—John W——, aged forty-six, a merchant of a neighboring State, was referred to me for the relief of stricture of the urethra, which at the time of his visit was to all intents and purposes impermeable. I found the fundus of the bladder midway between the symphysis pubis and umbilicus, and causing him considerable inconvenience. As was then my custom, a physiological dose of opium (two grains), combined with extract of belladonna (one-fourth grain), was prescribed, in order to allay spasmodic conditions if such existed. A hot sitz-bath (115° F.) of fifteen minutes' duration was also ordered. After much, though careful, effort, a small steel instrument passed the coarctation. He was requested to return the next day for further instrumentation. This time No. 12 passed easily. On the evening of the same day, I was summoned to him, and found that he had had a chill, that was followed by high fever, his temperature registering 104.5° F. at the time of my visit. His apartment, in a second-class hotel, being far from salubrious, the patient was at once removed to the hospital. Twenty-five grains of sodium salicylate every four hours was prescribed, prior to which, however, a fifteen-grain dose of calomel[1] was administered, to be followed in three hours by a seidlitz powder. Nevertheless, the pyrexia remained at 102° F. for a week later, notwithstanding the free use of antipyretic remedies.

On the fifth day an inflammatory swelling developed on the dorsum of the left hand, which resulted in the formation of an abscess with carbuncular characteristics. This abscess was freely opened, and treated with 1 to 2,000 solution of bichloride of mercury. Two days afterward a similar swelling appeared over the right temporo-maxillary articulation. An abscess also developed at this site, was freely incised, and treated antiseptically. During, and subsequent to, the developmental stage of this abscess, tetanic closure of the jaws took place, which lasted some time afterward, necessitating rectal feeding. The lymphatic ganglia were all more or less involved. Six weeks elapsed before the patient left the hospital, and during all this time the objective and subjective phenomena indicated intense septic infection. His unfortunate experience prejudiced him against further instrumental treatment.

I was much concerned about the complications occurring in this case, and naturally concluded that my instruments had carried the coccus septicus into the urethra. This conclusion would have been justified had I not always scrupulously cleansed my instruments after use. Neither had I previously used them in a case where I could suspect a *causa movens*. I can assume either that the necessary mycotic element existed *in situ*, and that the traumatism stimulated its activity, or that septic material still adhered to my instrument, notwithstanding its careful cleansing.

CASE II. *Traumatic Stricture of the Urethra—Urinary Abscesses and Fistulæ—Treatment by Continuous Dilatation and Persistent Drain through a Catheter for Three Weeks—Recovery.*—About ten years ago I published[1] a case of impermeable stricture of the urethra, complicated by a large number of urinary fistulæ, in which I permitted the patient to attend to his avocation, with an ordinary catheter of the shops tied in his urethra. His position as foreman of a large car-stable necessitated much movement, and the case was certainly a fair test of the practicability of the method. Dittel,[2] commenting favorably upon the perfect result, asked "why I had not used silver instruments?" The reason seemed to me obvious, and any explanation unnecessary. I may state, in addition, that for eight years after he was discharged, and until the time he was killed by an engine of the Fire Department, not an instrument was used for the evacuation of his bladder or the treatment of his stricture. The case simply proved that perineal section was not the remedy *per se* for such difficulties, and that organic stricture of the urethra can be cured, even though we cannot remove all the cicatricial tissue surrounding the canal. Further, that the removal of urinary friction and contact are the means to an end in the treatment. A similar case[3] recently presented itself at my clinic.

D. F. K——, aged forty nine, has always been well up to July, 1881, excepting one attack of gonorrhœa which he contracted during the war. It lasted but two weeks, and was controlled by balsam of copaiba. During July, 1881, patient fell astraddle a plank fence, injuring the perineum. Swelling of the genitals followed in half an hour. Patient was bed-fast for two weeks. No history of urethral hemorrhage. No record of sudden retention. During these two weeks, and for three months afterward, the urinary stream became gradually reduced in diameter, and at the end of this time the first complete retention occurred. This was relieved by cocaine injections and silver catheter. He used the instrument off and on for a year, when the second urinary retention occurred. About this time urinary infiltration and abscesses ensued, followed by fistulous tracts. Ever since that time repeated attacks of retention, abscesses, and fistulæ developed, the most of his urine passing through the fistulæ.

When I examined him, the evidence of urethral mischief was apparent. The scrotum and perineum were riddled with old, healed tracts, patent canals, and several in the process of formation. The latter were left untouched though the purulent collection was prominent. An examination of the canal and introduction of soft instruments eventuated in the passage, with some difficulty, of a No. 4

[1] The revival of calomel administration in the initiatory stages of mycotic disease is undoubtedly a wise precaution. By this means the constitution is freed to a large extent of mycotic elements, and the formation of ptomaïnes lessened. The action of calomel upon the kidneys and intestines particularly favors this agent.

[1] The loss of the journal containing this report forces me to rely on my memory. I believe it appeared in the Philadelphia Medical and Surgical Reporter.

[2] Centralblatt für Chirurgie.

[3] The case of McCabe was a traumatism to the membranous urethra, following a fall from a horse.

A. S. ordinary gum elastic catheter. Every effort to pass a larger steel instrument resulted negatively. The question now arose, Shall perineal section be advised, or should my experience with the McCabe case be repeated? The former was impractical, because he refused to enter a charity hospital, and his means would not permit him to go to bed. I chose the catheter *à demeure*, and fixed No. 4 of the shops in his canal. He was sent home, and advised to continue his avocation. This he did, and returned the next day. The catheter was quite movable, and had caused him no inconvenience, though his occupation necessitated much walking. Some urine had passed along the sides of the instrument. No difficulty was experienced in fixing a No. 7 instrument in the same manner as before. The next day a similar report was received, excepting that no urine had passed alongside of the catheter. No. 10 was introduced and fixed similarly. On the fourth day No. 12 was passed and stationed as before. When he returned the succeeding day, he reported a slight vesical tenesmus, which I attributed to the proximal tip of the instrument irritating the bladder. Not having a larger catheter at hand, the treatment was varied somewhat. Steel instruments were used hereafter; the patient was directed, however, not to micturate voluntarily under any circumstances, but to introduce a No. 12 instrument whenever he felt a desire to pass water. Three weeks have elapsed (treatment was interrupted five days, patient being out of the city) since treatment began, and No. 28 F. can be introduced with little difficulty. Indeed, the stricture seizure upon the instrument is gradually lessening, an evidence of import, and an indication that the cicatricial tissue is losing its contractility.

Though this case is still under observation, and a final judgment not yet permissible, I have reason to believe that success is as hopeful as in the case of McCabe. That the treatment pursued embodies the principles of urinary drain through the perineum, the vesical trigone, or suprapubic section, is self-evident. That it enables the patient to pursue his avocation unhindered is proven, and must take precedence over any operative procedure. That the treatment can be pursued indefinitely without producing irritation,[1] or calcareous deposit upon the proximal tip can be assured. That it is not as rapid in its results, and does not offer the opportunity for surgical *finesse*, is compensated for by the ability afforded the patient to follow his vocation without interference; and in fine, it offers as good an opportunity of permanent relief as any operation heretofore suggested.

SUDDEN AND PROFUSE HEMORRHAGE DURING LABOR.

By L. N. SHARP, M.D.,

MINNEAPOLIS, MINN.

Having recently attended an obstetrical case with a peculiarity, I thought it worthy of record.

Mrs. C——, eight months pregnant, had labor pains all day, with occasional vomiting, and thinking she was going to be delivered, sent for me at 5 P.M. On arrival she was having pains quite regularly and frequently, and examination showed the os to be dilated to about the size of a quarter of a dollar. A little later while sitting on a chair, and while vomiting, she had quite an extensive hemorrhage from the vagina. The blood ran through her clothing and down over the floor. I ordered her in bed, and labor progressed with but little more discharge of blood. At 10.30 the "waters" broke, and as the child lingered in the pelvis, I delivered with forceps at 12.30 in the morning. There was no sign of life in the child, no pulsations in the cord or fœtal heart.

My understanding of her case is that during the vomiting the placenta was completely detached, and hence the hemorrhage. The condition of cord and child favor this conclusion. I was not able with the finger to detect the placenta at any time during labor, and do not think the attachment was near the os.

[1] The following precaution must be adopted: The tip of the instrument must rest in the vesical end of the prostatic urethra. This prevents vesical irritation and calcareous deposit.

PITCHFORK WOUND OF THE NECK.

By W. H. STROUP, M.D.,

SPENCER, O.

On the evening of October 29, 1891, I was summoned to see a boy, fifteen years old, who had fallen from a load of hay on a pitchfork which he had on the load. On examination I found that one of the fork-tines had penetrated the neck, passing clear through. It entered on the right side just above the clavicle, passing back of the common carotid artery, but pierced the internal jugular vein, and made its exit on the opposite side, but considerably posteriorly.

During the first few hours he vomited a great deal, was dizzy when he opened his eyes, was somewhat comatose, and the pupils were irregularly dilated. There was retention of urine.

Gradually these symptoms subsided, and the boy is now able to be around. I think the vomiting was due to injury to the vagus nerve. The ocular symptoms and retention of urine pointed to head injury. I forgot to mention that he had severe frontal headache. The treatment was cold to the head, arnica to the neck, and the other treatment was symptomatic.

A NEW PROCEDURE IN EXTRACTION OF CATARACT IN ITS CAPSULE.

By GEORGE H. POWERS, M.D.,

SAN FRANCISCO, CAL.

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF CALIFORNIA.

Having been unable to find any notice of the previous use of the simple step which I have lately adopted to facilitate the removal of the capsule in cataract extractions, and as it seems to me to be possibly a very valuable improvement upon former methods, I briefly outline it here in the hope that other operators may give it a trial and publish their results. It consists simply in the detachment of the capsule by rotation. After completing the incision, I pass the point of the cystotome to, or a little beyond, the farther margin of the pupil, when, instead of lacerating the capsule, I plunge the point of the instrument well into the lens. It becomes then very easy to rotate the whole lens by gently moving the point of the cystotome thus embedded around the periphery of the pupil, just as one rotates a wheel by applying force to one point on the hub.

So far I have always found the attachments of the lens to be entirely severed without appreciable force and without accident or evil effect of any kind.

In ten or twelve operations lately made in this manner, two were quite soft, and in them a small portion of cortex was extruded from the minute wound in the capsule as the lens was pressed out of the globe, but this was easily removed and gave no trouble. I confidently recommend this procedure, and shall be glad to learn if it has ever been employed before.

215 Geary Street.

Notification of Infectious Diseases.—In London a physician receives a half-crown fee for each case of notification of contagious disease. In Connecticut also there is, or used to be, a fee of twenty-five cents for each notification of contagious disease and each birth certificate. If the New York authorities were equally just in their recognition of the doctor's right to be paid for his services there would doubtless be no need for the threats of prosecution by the health authorities, which are so often used to force physicians to obey the law in this respect.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 30, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	3
Scarlet fever	192	28
Cerebro-spinal meningitis	1	5

The Late Dr. David S. Smith.—The following minute was adopted at the last meeting of the Orange Mountain Medical Society: Dr. David S. Smith was born in Morris County, N. J., in 1831. He received his degree of M.D. in 1855, from the Medical Department of the University of New York. He commenced the practice of medicine at Irvington in 1855, continuing actively engaged in his professional work until his death from pneumonia, on December 8, 1891. He was married to Miss Laura Tichenor in 1861. Two children born to them died in childhood. The doctor was always interested in the public affairs in village, township, and county, from early manhood. He was superintendent of the schools in Irvington, and was a member of the Board of Freeholders for twelve years. He was an active member of the Road Board and the Lunacy Committee. There have been few interests or institutions in the county, in the inception or construction of which Dr. Smith has not taken an active part. He joined the Orange Mountain Medical Society in the first year of its existence, and was a regular and interested attendant at its meetings. He rarely allowed an opportunity for expressing his views on any subject to pass unimproved. He was always clear and certain in his opinions on medical subjects, and his judgment was generally correct. He carried the same earnestness and enthusiasm that marked his conduct in his relation to the general affairs of life, into his professional work. It is unusual to find so much shrewdness and administrative capacity combined with such broad humanity as characterized Dr. Smith. By the members of this Society he will be remembered particularly for his genial manner, his hearty humor, and his infectious laugh. We will cherish his memory and remember him as a member who never attended a meeting without making his presence felt by all present. William Pierson, John J. H. Love, *Committee;* J. W. Stickler, *Secretary.*

The Ptomaine of the Tobacco Bacteria varies the Flavor.—A somewhat surprising investigation, which the Department of Agriculture is conducting, has to do with tobacco. An important part of the curing of tobacco is its fermentation, which occurs during the process known as "bulking." The leaves are packed closely together in large piles, and after a while the mass heats, the tobacco, as is said, "sweats," and the aromatic compounds which contribute to its flavor and odor are formed. The phenomena of fermentation are caused by bacteria. Each kind of tobacco has its bacteria, which give it aroma and flavor incidentally to feeding upon it. It has been ascertained by experiment that poor tobacco, when inoculated with the bacteria naturally belonging to fine tobacco, obtains the flavor and quality of the latter. Thus by a simple operation it may be easy to transform inferior leaves into first-class material for cigars which the consumer may believe are from the Vuelta Abajo.

The Practitioners' Club of Chicago entertained and elected to honorary membership its guest, Victor C. Vaughan, Ph.C., M.D., Dean of the Department of Medecine and Surgery, University of Michigan, at the regular monthly banquet, held at the Palmer House, December 28, 1891. The subject for the evening, "Methods of Medical Instruction and their Results," was enthusiastically discussed, a division of opinion being held as to the merits of the systems now in use. Didactic teaching, in the main, was well favored, but very much from the undisputed fact that clinical instruction falls far short of what it should be. The graded recitation course had its adherents and seems to be gaining good opinion. The results of medical instruction and the effects of specialism and book-medicine, were treated in lighter vein, being largely delineations of shortcomings, personal and otherwise. Dr. Vaughan is the first to receive the honorary gift of this club. Professor E. L. Holmes, President of Rush Medical College, presided as chairman.

Medical Schools in Turkey.—There are five medical schools in the Turkish Empire—one at Constantinople, one at Cairo, one at Aintab in Northern Syria, and two at Beyrout, one of the latter being Protestant and the other Roman Catholic. Only the Constantinople and Cairo institutions possess the right of granting a license to practise; the other three, which are in the hands of missionaries, can only give certificates of study, candidates having to go to Constantinople to be examined. A diploma conferred by the Cairo school gives only the right to practise in Egypt; if a doctor who has obtained a diploma at Cairo wishes to practise in other parts of the Turkish Empire, he must pass a further examination at Constantinople.

A Second Attack of Varicella.—Dr. Richard Neale reports, in *The Lancet* of November 21, 1891, that he was called recently to attend a family of children for chicken-pox, one of whom, a boy aged five and one-half years, had all the symptoms of the complaint—numerous vesicles and considerable drowsiness—the attack running its usual course. Ten days after the disappearance of the acute symptoms, and when the child was on the point of being allowed out, a profuse crop of vesicles appeared, which were far more numerous than on the first occasion, and the patient again went through all the stages of the original attack, the constitutional disturbance being but slight.

A Miracle Worker.—Señorita Teresa Urrea by name has appeared in a town in Sonora, Mexico, and is creating a great excitement among the country folk in the neighborhood of her father's hacienda. She is already credited with over three hundred cures of the lame, the halt, and the blind.

Diphtheria has been prevailing to an unusual extent in Milan during the past autumn, and previous to that there was a severe outbreak of typhoid fever. The water supply of the city is said to be exceptionally bad.

The International Executive Committee of the Pan-American Medical Congress.—The Committee on Organization of the Pan-American Medical Congress, at its meeting at St. Louis, last October, elected the following International Executive Committee: *The Argentine Republic*, Dr. Pedro Lagleyze, Buenos Ayres; *Bolivia*, Dr. Emeho di Tomassi, La Paz; *Brazil*, Dr. Carlos Costa, Rio de Janeiro; *British North America*, Dr. James F. W. Ross, Toronto; *British West Indies*, Dr. James A. De Wolf, Port of Spain; *Chili*, Dr. Moises Amaral, Santiago; *United States of Colombia*, Dr. P. M. Ibañez, Bogota; *Costa Rica*, Dr. Daniel Nuñez, San José; *Ecuador*, Dr. Ricardo Cucalon, Guayquil; *Guatemala*, Dr. José Monteris, Guatemala Neuva; *Hayti*, Dr. D. Lamothe, Port au Prince; *Spanish Honduras*, Dr. George Bernhardt, Tegucigalpa; *Mexico*, Dr. Tomás Noriega, City of Mexico; *Nicaragua*, Dr. J. I. Urtecho, Grenada; *Peru*, Dr. J. Casamira Ulloa, Lima; *Salvador*,

Dr. David J. Guzman, San Salvador; *Spanish West Indies*, Dr. Juan Santos Fernandez, Havana; *United States*, Dr. A. Vander Veer, Albany, N. Y.; *Uruguay*, Dr. Jacinto De Leon, Montevideo; *Venezuela*, Dr. Elias Rodriguez, Caracas; Hawaii, Paraguay, Santo Domingo, the Danish, Dutch, and French West Indies are not yet organized. Nominations of local officers have been received from a majority of all the members of the International Executive Committee, and a number of the lists have been confirmed by the Committee on Organization. These will be announced as rapidly as acceptances are received. CHARLES A. L. REED, *Secretary-General.*

The New York Ophthalmological Society.—At the annual meeting, held on Monday, January 11th, the following officers were elected: *President*, Dr. J. B. Emerson; *Vice-Presiaent*, Dr. Gorham Bacon; *Secretary and Treasurer*, Dr. Frank N. Lewis, *Committee on Admissions* Dr. H. D. Noyes, Dr. A. Mathewson, and Dr. C. E. Hackley.

The Electricians on Electrocution.—Our contemporaries in the electrical world are inclined to differ in opinion, as well as in sentiment, about the application of electricity for the carrying out of the death penalty. One weekly review of electricity is far more severe in its strictures than we have been. This journal speaks of the electrical executioners as "electro-butchers," and describes the details of the new process "of electrocution" as causing such horror and disgust that nothing would induce it to reproduce in its columns the latest account. Above all, it is shocked that any electrician could be found "of so degraded a mind as to lend any hand in so loathsome a task;" and "regrets extremely that any among those qualifying for the pursuit of the youngest, and in many respects the most advanced, of the sciences, should be found willing to put their knowledge to such a debased and debasing use."—*Lancet.*

Something New to Eat.—A new vegetable is about to be introduced to the people of the United States, through the Department of Agriculture. It is the root of the calla lily, which resembles somewhat in appearance the ordinary Irish tuber, with the addition of a few whiskers that have nothing to do with the qualities of the article as an esculent. It is more elongated, and when cut the interior is a trifle more viscid; but a section of it is so potato like you would not be likely to distinguish any difference. In cooking, it has first to be boiled in order to destroy certain acrid properties, after which it may be fried, roasted, baked, or what not, according to taste. Farmers in Florida have begun to raise these calla roots for market. The plants grow readily in swamps, and so thickly that the yield of a single flooded acre is enormous. They reproduce themselves by the multiplication of their bulbs underground, so that the grower has simply to dig up the offshoots and leave the parents to propagate anew. For centuries the Egyptians have cultivated a similar crop during the seasons of the Nile overflow, and at the present time calla lily bulbs are a common vegetable in Japanese markets. So prolific and palatable are they that their propagation in many parts of the United States, where conditions are favorable, may reasonably be looked forward to as an agricultural industry of the future.—*Portland Oregonian.*

The Ways of Invalids on the Riviera.—The medical adviser to the Paris *Galignani's Messenger* gives certain instructions to invalids visiting the Riviera which, if followed, would make them somewhat conspicuous objects among the orange and lilac groves of the sunny South. All invalids, we are told, should go indoors before the sun sets and not go out before it rises. When going from the sun into the shade they must put on additional clothing. Then they are advised to carry a sun umbrella, to wear smoked eye-glasses in the bright sunshine, and not to overdress or walk too fast. Lastly, when entering the house, not to remove their outer coverings at once. Unless the invalid is a lunatic, the advice about not going out before sunrise should be superfluous. How he is to adjust his clothing to the varying requirements of sun or shade we are not informed. It is cutting things rather fine to expect one to don a second overcoat while passing beneath the shade of a tree. The smoked spectacles are ugly, but they are part of the invalid's uniform. On the whole, it is doubtful whether it is worth travelling six or seven hundred miles to submit to such irksome restrictions.—*Hospital Gazette.*

A Model Death Certificate.—The following is a *verbatim* copy of a certificate of death in the case of a man in Maryland who accidentally shot himself:

"BALTIMORE COUNTIE November the 22. 1891

"This is to surtifie the. a gustc of the Peace of Baltimore countie held an inquest on the Body of William Harmer came to his Deth by a gone sot wond in his one hands. With too young frends Georg Young and Jacob Willis in company at or near John Allis fishing shore."

Embalming appears to be a very expensive luxury. A Russian newspaper states that Professor M. A. Popow, of Charkow, received a fee of 2,500 roubles ($1,250) for embalming the body of the late Grand Duke Nicholas. The fees of Professor A. L. Podres, of the same university, for medical attendance on the Grand Duke amounted to 2,000 roubles ($1,000). From this it might perhaps be inferred that in the case of royal personages it is sometimes considered less important to keep them alive than to preserve their remains when dead.—*British Medical Journal.*

A Scientist's Ruling Passion.—Dr. Richet, whose death occurred recently, made careful observations on his subjective symptoms, detailing them to his son and the attending physician in order that they might write them down. Each new sensation was minutely described, and even at the very end, when those about observed unmistakable signs of speedy dissolution, he surprised them all by saying, "You see I am dying."

Consultation with Juniors.—A correspondent raises the question as to the proper conduct of a medical man who is asked to call a younger member of the profession into consultation. The question, however, answers itself. Professional skill is not to be measured by years, and if it were, the inference would often, within certain limits, be in favor of the younger man. Again, it may be disagreeable for a practitioner to be asked to consult with one inferior to himself, so far as degrees are concerned, in the medical hierarchy, but he can always vindicate his dignity by withdrawing from the case. The patient's wish in such a matter is law, and he cannot be expected to enter into petty details of precedence when health and life are conceived to be at stake.—*Medical Press.*

For External Use.—In some parts of Germany all fluid remedies for external use must be put up in hexagonal bottles with ribbed sides, and having a red label. Internal remedies, on the other hand, are dispensed in smooth round bottles with a white label. Unfortunately, there are people so stupid or so careless that even this will not save them from making mistakes.

A Simple Cure.—A case of incontinence of urine in a little girl has been related to us. The attending physician prescribed a number of remedies, but the urine persisted in coming, drop by drop. Another physician who was called in examined the child, and removed from the urethra a hairpin which had kept it patent. It is needless to add that the disease was cured.—*Weekly Medical Review.*

What in the World Is It?—The Paris correspondent of *The Lancet* speaks of infancy as the period associated with "the wearing of swaddling clothes, or the sucking of that comforting toy called, I believe, by our American cousins, a 'chew-gum.'"

CONGENITAL BILATERAL AND SYMMETRICAL CARTILAGES ON THE NECK, AND THEIR MORPHOLOGICAL SIGNIFICANCE.[1]

BY CARL BECK, M.D.,

PATHOLOGIST TO ST. ELIZABETH'S HOSPITAL, CHICAGO, ILL.

SINCE embryology has revealed the development of the single parts of the human body, and comparative anatomy has brought out the signification of some organs which do not reach their full development in man, abnormities hitherto not understood or misapprehended have been explained. Even such abnormities which considered as possible, had been *a priori* constructed, have been recorded since, thus proving the correctness of the theory.

Abnormities of development from the ideal construction always have much interest, especially when there is some regularity in the reappearance of them, so that they form a well-determined class, which of course raises the idea in our mind that a certain cause is common to all.

But in embryological studies comparative anatomy must always have a leading place, as Professor Milnes Marshall so aptly expressed in his address to the Biological Section at the meeting of the British Association for the Advancement of Science.[2]

"Embryology has thriven mightily of late years; but the watching of all the processes of the development was of trifling account, compared with the great generalization, which showed that the development of animals had a far higher meaning. The phases through which an animal passed in its own development were no accidental freaks, but represented more or less closely, in more or less modified manner, the successive ancestral stages through which the present condition had been acquired. Evolution told us that each animal had a pedigree in the past, and embryology revealed to us this ancestry, because every animal in its own development revealed this history."

From this standpoint we shall examine the present case:

History.—John B——, aged forty-eight, laborer on the railroad, received an injury in an accident, crushing his great toe. The primary operation giving no satisfactory result, he was transferred to the Alexian Brothers Hospital, where I happened to be present at the operation performed by Dr. Oswaldt. While he was under chloroform I noticed on the right side of his neck a projecting spot, on the inner border of the sterno cleido mastoideus, about on the level of the cartilago cricoideo, which proved to be a little hard body, movable but closely connected with the deeper tissues. The first idea was, it might be a foreign body, but when we found a corresponding small body on the left side I suggested the removal of a particle, in order to make a microscopical examination. When the skin was cut and the superficial tissue split, we noticed that the small body was very adherent to the deeper tissue, and with a part going farther down behind the muscle.

The removed particle gave the following appearance when examined: A cut through the specimen shows that the same is a part of a reticulated cartilage, on one side covered with perichondrium, which contains more cellular elements than usual. The boundary between the cartilage and the perichondrium is very well defined, forming a sharp line. (Only in one specimen of six can cartilage tissue be seen breaking through this line.) The cartilage itself has many small single cells near the boundary, the nuclei being spindle-shaped and with the long axis parallel to the boundary line, and on some points this direction extends downward toward the centre, forming bundles of cells lying in a network of fine connective tissue, these bundles being surrounded by a coarser network. The whole represents what we histologically call reticulated cartilage (cartilage réticulé—Netzknorpel). The examination of the patient showed that there was no trace of a fistula of the neck, no tumor, no enlarged glands in this region. The cartilage of the right side, that is the small particle which was left under the inner border of the sterno-cleido-mastoideus, was firmly connected with the tissues below. The left one was more flattened, larger, and had some serrations on the exterior edge; it was movable, but held by an elastic portion under the muscle.

When the patient swallowed the cartilages did not move, showing that they were not attached to the tracheal tractus. There was no other abnormity on the body. The patient had noticed these little particles himself, when a small boy, and says that they have not apparently grown since.

Cases of congenital cartilages on the neck have been described by different writers, but I find only very few cases which resemble the present. Those recorded by Poirier and Retterer,[1] were either not symmetrical or were in connection with other malformations or tumors of the neck, as the congenital branchial fistules and cysts. The latter have been studied only of late, and only understood when through embryological facts it was ascertained, that they were products of the arrest of the development or subsequent changes of that pathological condition. In such descriptions I find the first trace of this abnormity.

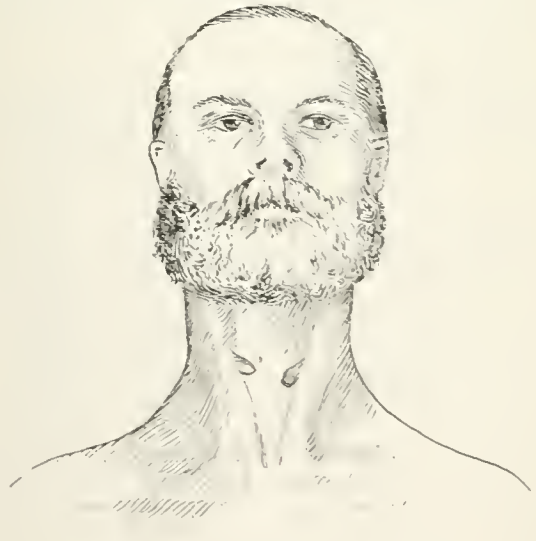

FIG. 1.

Heusinger,[2] who first investigated this matter thoroughly, gave at that early period a good and probable explanation.

[1] Read before the Chicago Medical Society, November 2, 1891. MEDICAL RECORD, November 15, 1890.

[1] Poirier et Retterer: Cartilage branchial bilatéral et symmétrique, Journal d'Anat. et Phys. Paris, 1890, xxvi., 49–62.

[2] Heusinger: Archiv für path. Anatomie und Physiol., Bd. 33, S. 179 und 441.

Since the attention of the embryologists was drawn to the subject, the opinions of all the authors agreed in that one point, that the abnormities have something to do with branchial arches, but disagree concerning the way in which they are derived from the same. In order to investigate this I give an account of the embryological facts, which are homologous throughout the whole system of such progressive modifications, complications, and adaptations, as occur under well-known laws. The main law of development of the body is that of a segmentation of the frame of the same; the segments remain more simple in the lower classes of animals, but gradually differentiate themselves in the higher, so that two members of two different classes at their full development are very unlike, but, as each embryo repeats the whole ancestral differentiation, they are at a certain stage of the development very similar.

Concerning the evolution of the segments, which have relation to our abnormities, we follow the explanation of Gegenbauer.[1]

A number of such primitive segments form from a certain class, beginning with a distinct head and neck at the commencement of the alimentary canal, both being formed by a certain number of arch-like bodies similar to the ribs of the vertebral column, being at first primitively cartilaginous; but at the same time they are not altogether homodynamous with ribs. The various arches differ in form, but they all give indications of having been primitively similar. Their difference in form is due to a differentiation which has been brought about by adaption to different conditions. These arches, being connected with the most anterior portion of the axial skeleton, form the organs of support for that portion of the alimentary canal as well as the respiratory cavity. The number of arches and the backward extension of this apparatus depend on the size of this respiratory cavity. The first type is found in the acrania (amphiosus lanceolatus). In this framework there is a cartilaginous arch around the mouth, that is, in its most anterior portion; this arch is composed of cartilaginous rods, which are directed forward. The rest of the apparatus is formed of a homogeneous substance, which forms, as in balanoglossus, a complicated lattice-work. The branchial bars of either side are independent of those on the other, that is to say, they are not united along the ventral line.

We cannot derive the second type which obtains in the craniola directly from this. In its earliest stage it is made up of cartilaginous pieces only; these do not form as large a number of arches as exist in amphioxus, and are, while completely symmetrical as regards their arrangement, united ventrally by a copula.

In the cyclostomata the branchial skeleton is made up of complicated cartilaginous bars, which are connected inferiorly with one another as well as with either side of the spinal column superiorly. Owing to their superficial position they may be spoken of as forming an external branchial framework. Very evident signs of this are retained by the selachii, but in them there is another or internal organ of support, which is found in all the rest of the vertebrata. The various arches present indications of their primitive similarity, this disappears in consequence of the gradual change in their functional relation, which is due to a division of labor. All these arches evidently had the same original function; their relation to the respiratory apparatus has not disappeared in the first pair, which have been duly converted into jaws. The hinder arches also have gradually lost their functional and anatomical characters. It is therefore reasonable to suppose that this is but the last of a series of reductions, which first commenced on a much larger number of arches. This view is supported by a comparison with amphioxus, as well as by the consideration, to which we are led by the studies of the branchial apparatus and peripheral nervous system. As we pass through the fishes to the amphibia, we may note how this apparatus gradually loses its primitive relations, while in the reptilia and all higher forms it has no relations at all to the respiratory organs.

What becomes of these arches in the higher classes, and particularly in the human embryo?

At a certain early stage of the development that part of the body which afterward forms the face and neck consists of four indifferent arch-like bodies; the way by which they develop into their final shape has been studied with the greatest detail.

At first the arches, which close in the median anterior line, are separated by grooves or clefts. It has not been ascertained, whether or not there is a real cleft or a very thin but closing membrane between the single arches, though the opinion of the best embryologists, as His,[1] Kölliker,[2] Born,[3] is that in the human embryo there are no clefts. H. Foll,[4] P. de Meuron,[5] and Katschenko[6] stated, through their studies made on sections which had been prepared with the best technological method, that there is a real canal and that the epithelium of the entoderm passes directly over into the ectoderm. This opening is only during an early period and with the exception of the first, closes again.

After the fourth week a further differentiation of the arches takes place. The first and second arches are growing fast, and while the upper one overlaps the lower one on the outside, the reverse takes place inside, so that they slide one into the other like the tubes of a telescope. In consequence of this unequal growth of the arches a sinus is formed in front, in the depth of which the third and fourth arch are found, while its entrance is bounded anteriorly by the second or hyoid arch. The sinus is called sinus cervicalis (Rabl[7]). The hyoid arch extends into a small process, which overlaps the sinus cervicalis and closes the same in connection with the retro-bronchial processes and the thoracic wall, which arches over the sinus (Kauthak[8]).

If this sinus remains open a fistula of the neck results, which would lead into the pharynx if one of the clefts remained open or if the membrane breaks. From the accessory organs, which are the products of the arches, the concha of the ear is most interesting for us, as many writers are inclined to bring abnormities like the present into relation with the same. And, in fact, the first development of the concha bears much similarity with the symmetrical cartilages. We are indebted to Moldenhauer[9] and His[10] and Katschenko[11] for their thorough studies of this subject. According to them, around the external lateral end of the first cleft a small ridge arises, containing some cartilaginous nodules, which getting more and more distant from the surface, form the tragus, antitragus, helix, etc.

Having discussed the development of the parts of the body which have some reference to our case, we are going to answer the question, Which is the part from which our cartilages are derived, and what is their pathological significance?

There are *a priori* several possibilities:

That they are aberring germs in the sense of Cohnheim, can be *a limine* rejected, on account of the symmetry and regular reappearance in the same place.

Another possibility, which is more comprehensible than

[11] Katschenko: Loc. cit.

probable, is that these symmetric cartilages we meet with are aberring particles of a symmetric superficial cartilaginous tissue of the same histological construction of the neighborhood, and that would be the external ear, or perhaps an analogue of the ear derived from one of the lower arches. There are really often found cartilaginous nodules (supernumerary cartilages) in the neighborhood of the ear, and that they even can imitate the shape of the concha a case proves which was described by James Cantlie, from Hong-Kong, in the *Lancet*, 1890.[1]

Many authors are of either one of these opinions. Kostanecky and Mielecky[2] gathered, in their very instructive paper on congenital fistules of the neck, the literature about this subject and offered their own opinion.

According to them, Heusinger, who first noticed this abnormity at all, adjudged that any visceral arch can form cartilages, if the original cartilage fails to disappear and afterward grows. On account of the position they form the third arch. Broca's opinion is that inasmuch as the fourth visceral arch does not form any cartilaginous nor bony parts in the embryo, the cartilage of this arch sometimes remains abnormally, but generally disappears (Cusset).

Callendar is of the opinion that these cartilages are formed from those which are intended for the development of the hyoid bone and larynx by differentiation. Bland Sutton points out that in the embryo every cleft is covered by the higher one by operculum, which retains the permanent state in the selachii. He considers the auricle as a big operculum modified for hearing purposes, and he supposes that also the other clefts are covered by such opercula. He calls them supernumerary auricles. Hennes considers them as residues of embryonal branchial arches, and as their typical position corresponds with the congenital fistule of the neck, the origin may be the second arch or cleft. Virchow, who observed a case of a cyst containing an oily fluid with a cartilage plate in its wall, which was found in front of the carotid artery, regards the whole as a meatus auditorius externus with the tragus, and calls it an auricular teratom. He says: "There is no doubt, if one compares a number of such abnormities, that particles of the ear are met with which have been destined for the external canal, but through a deviation in the first formation took a heterotop position," and according to this view, he calls them abgesprengte auriculäre Enchondrome (misplaced auricular enchondromata).

Finally, Kostanecky and Mielecky give their own opinion: "We believe," they say, "that as there never was noticed a relation between these apophyses and the visceral skeleton, and the occurrence of such processes does not involve any disturbances or anomalies in the development of the visceral skeleton, the supposition that these cartilages are isolated, and afterward independently growing parts of the visceral skeleton, is false, and that we have to do with an embryonal growth. But we have no reliable cause to suppose that these growths consist in a repetition of parts of the visceral skeleton itself. On account of their generally very superficial position, we can exclude a participation of the third or fourth arch as origin, and must refer to the operculum (Kiemendeckelfortsatz) of the second arch for those of the neck, for those of the face to the operculum of the first arch. With regard to the origin from the same arches, their position and microscopical texture, we believe, therefore, that they are heterotopic homologies of those parts, from which the auricle is developed, wherefore their name as auricular anhänge abnorm, accessorial ears, seems to be justified."

Poirier and Retterer,[1] who found an abnormity exactly resembling the present on the dissection-table, were able to investigate the case thoroughly. The dissection showed that the fibres of the platysma myoides were going below the surface of the little tumors, the external jugular vein in front of them, the adherence to the aponeuroses of the sterno-cleido-mastoid was very intimate, and at last the fibrous tissue of the hard masses extending deeply, was lost trace of in the level of the sheath of the large vessels. Larynx and pharynx showed no connection nor abnormity whatever. The outer portion of the cartilages was round-shaped, the inner portion more flattened. After minute examination of all the points which have some reference to this question, they reach the conclusion that these little tumors, having much resemblance to those apophyses which give origin to the external ear, are of the same morphological significance, being only derived from one of the last arches.

If we make a *résumé* of these views, we find that, with a few exceptions, all the authors refer to the operculum of one of the arches as the origin of the congenital symmetric cartilages.

The opercula are symmetrical, it is true, the tissue is fibro-cartilage in the ear and also in these growths, but nevertheless the other explanation seems more plausible.

If we look at the matter from the standpoint of comparative anatomy, we must say that the idea of a reappearance of a second ear, which does not exist in the whole series of the system of animals, is somewhat affected; we find that cartilages on the neck appear in all the classes of animals, and while very exceptional in man, they are, as Heusinger [2] has already observed, more frequent in some other classes of the mammalia, and still more so in the lower classes; they are the same cartilages which support the respiratory system in the fishes, and belong therefore to the visceral skeleton.

Kostanecky observes that they are generally very superficial, while in the present case, and in all the rest of them, it was noticed that they extended very deeply and even down to the sheath of the large vessels, as in Virchow's case.

Duplay [3] describes a case of a child five years of age, with an abnormity like the present, where the cartilages were movable, but with a part growing far under the sterno-cleido-mastoid.

P. Buttersack [4] observed a case, twenty-three years of age, and made the same observation, that the deeper part of the cartilage was in intimate connection with the lower tissues.

Poirier et Retterer [5] make the same remark, that the cartilages extended down into the sheath of the vessels. An abnormity of a second, parallel ear has no analogue in the evolution; polyotie has quite another meaning.

Schultze,[6] one of the oldest writers on this subject, gave, without knowing the characteristic details of the embryological development, this explanation of the abnormity, of which he had a case. He says: "About the genetic significance, we can say that we have to do with an original abnormity of the branchial arches. They are neither growths *sensu strictiori*, nor accidental, nor derived from the auricle, as they are nowhere in connection with the latter."

We have to deal with an atavistic phenomenon, then. What is atavism? Atavism is the reappearance of anatomico-physiological characters, either positive or negative,

[1] Unilateral absence of ear, bilateral supernumerary auricles and developmental deformity of right side of face and features, by James Cantlie, F.R.C.S.

A Chinese male, thirty-eight years of age, had, one inch and a half in front of the lip of the mastoid process, and one inch below the level of the same, a heap of tough subcutaneous cartilaginous tissue with a depression or concha near the centre. This might be regarded as the representative of the right missing ear, but that it is not so may be seen by examining and studying the conditions met with on the left side. The left side shows a perfect ear, but in front of that again are subcutaneous tough cartilaginous tissues with a central depression (concha-like) almost identical with the excrescence on the right.

n an individual or in a group of such, which were not characters of their immediate parents, but of their direct or collateral ancestors. Darwin[1] states that all the rudimentary organs, useless for the animal, are atavistic, and which he compares them very aptly to the letters of a word, which are saved in the writing, but lost in the pronunciation, and are merely the clew which leads to their etymology. This etymology of the animals is given in the series of animals by those phenomenal appearances of what we call regressive metamorphoses; that is, it seems that in the development of animals a tendency is produced toward the superior original state. We know, for instance, from the studies of P. Fischer, that the embryo of the oyster represents a more perfect animal than the adult. It possesses a locomotor apparatus which allows him to swim rapidly, and has ear and eye which disappear afterward. Our abnormity would come under the head of reversion of the Darwinian subdivisions. Our conclusion is, therefore, that our cartilages are reversionary or rudimentary parts of the branchial cartilage system.

The arch to which they belong can be only the third or fourth one. We have to answer the question, in what connection they are to the branchial cysts and fistules. Many writers have described cysts with cartilaginous particles in the wall of the same, and fistules with cartilages in the edges have been observed also. That such abnormities are combined is only a proof of the theoretical explanation that they are rudiments, as the fistules are nothing but modified clefts, and cysts only pathological changes of preformed epithelial inclusions or embryonal cavities. But the symmetric, and reappearing with such regularity on the same place, cartilages are quite different from the accidental group of cartilaginous cells, which can just as well be connective tissue changed into cartilage. Regarding the question, if such cartilages occasionally can have some pathological significance, there are some very interesting observations. Since the attention of surgeons has been called to such abnormal residues of the development, some until then misjudged tumors of the neck have been satisfactorily explained. Volkmann's branchiogen carcinoma, which originates on the neck and, as it has been proved, takes its origin from remaining embryonal epithelial tissue, has been observed several times and proves Cohnheim's theory of the cause of the tumors.[2]

Branchiogen enchondroma is a term which has not been used very often in pathology, but of which cases are on record already, and which will be met in future perhaps more often, when attention is called to it. Zahn describes such a case, and I find in the earlier literature several cases which could be classed under this head, and could be started from such a matrix as our abnormal cartilages.[3] Heusinger[4] describes a case of a large tumor of the neck consisting of homogeneous cartilage, which contained hundreds of small cysts, and he called this tumor a cystoid enchondrom. The genesis, according to his term, verknorpettes Cystoid, would be that it was primarily a cyst, perhaps a multilocular cyst, in the walls of which cartilage tissue was growing; but it seems that it was rather a branchiogen enchondroma with cystic degeneration, which always takes place if the nutrition is at variance with the growth. In the same paper, Heusinger quotes another such case, and in his division of cystic growths the cartilaginous cysts with different contents form one subdivision. Zahn mentions that among the cases of tumors of the neck, the case of one operated on by H. J. Schäffer and examined by C. O. Weber, seems to be such a tumor as has just been described. It was a growth of the size of an egg on the side of the neck of a young man, movable under the skin, for several years growing steadily without pain, and which, though above the lower lobe of the parotid and in front of it, was in no connection with the latter. The hyaline, partly granular cartilaginous matrix changed toward the centre into more reticular and fibrous cartilage, the fibres crossing in different directions.

The enchondromatous tumors are more peculiar to the juvenile age. According to Virchow, groups of cartilaginous cells, which are included in bone-tissue, sometimes develop into enchondromata during puberty, and Zahn believes that this law could have the same value for tumors of the branchial arches. Whether a traumatism has an influence or not it is hard to decide, as the trauma and the cold are the trivial and insignificant causes which are generally made responsible where we cannot find any better. The statistics and the histories

FIG. 2.—*a*, Perichondrium; *b*, cellul. sub-perich. primit.; *c*, reticulum.

of the cases recorded until now would speak against both views, as in fourteen cases eight had passed the puberal age, and in many cases, though the cartilages have been exposed to traumatic influences, and in the case of P. Buttersack had been attacked very roughly, they had not developed into enchondromata.

But we know especially about the cartilaginous tissue, more than about any other in regard to its capacity to grow, from the experiments of Zahn and Leopold, made in the institute of Cohnheim. It was stated that cartilaginous tissue, taken from an unborn embryo, grew out into an enchondromatous tumor when implanted into the peritoneal cavity or corneal chamber of the eye. May it not be that these embryonal cells exist in such groups included in the normal tissue, and, if they do not lose their faculty to grow, or if they are irritated by some cause unknown yet, really grow out into the tumor. It is certainly remarkable, that we sometimes see such beginning of a tumor, if we can call it so. Zahn, at least, explains in one of his cases the fact that he found cartilage cells and groups of cells spread in the perichondrium, this way, and in my specimens I was able to find such a condition, and I explained it independently in the same way. We see the small cells right under the perichondrial boundary line very well defined (Fig. 2), and in one specimen we see this line broken and cartilage cells extending into the perichondrium, particularly those small cells which are the primitive or fundamental cells (Fig. 3).

[1] Darwin: Descent of Man.

[2] Cohnheim: Lectures on General Pathology, ii., p. 749. True, if you ask me wherein the abnormality in the disposition of the embryo consists that becomes the starting-point and cause of a tumor, I can only answer with hypotheses; the simplest view appears to me undoubtedly to be, that in an early stage of embryonic development, more cells are produced than are required for building up the part concerned, so that there remains unappropriated a quantity of cells—it may be very few in number—which, owing to their embryonic character, are endowed with a marked capacity for proliferation.

[3] There have been enchondromata observed in the parotis and testicle, and other organs which originally do not contain cartilaginous tissue, and especially in the parotis. They have been explained as remnants of the branchial arches, which explanation has been rejected on account of satisfactory reasons, but the whole matter is not cleared up fully yet.

[4] Heusinger: Loc. cit.

Whether these cells, which at any rate are abnormal, are the beginning or the starting-point of a tumor, or only supernumerary cells in the sense of Cohnheim, which can grow out into a tumor, I will not decide, but the shade

FIG. 3.—*a*, Perichondrium; *b*, cellul. sub-perich. primit.; *c*, reticulum; *d*, cellul. sub-perich. luxuriantes.

between these two possibilities is very slight. It may be that further observation of cases like the present will throw more light upon this question.

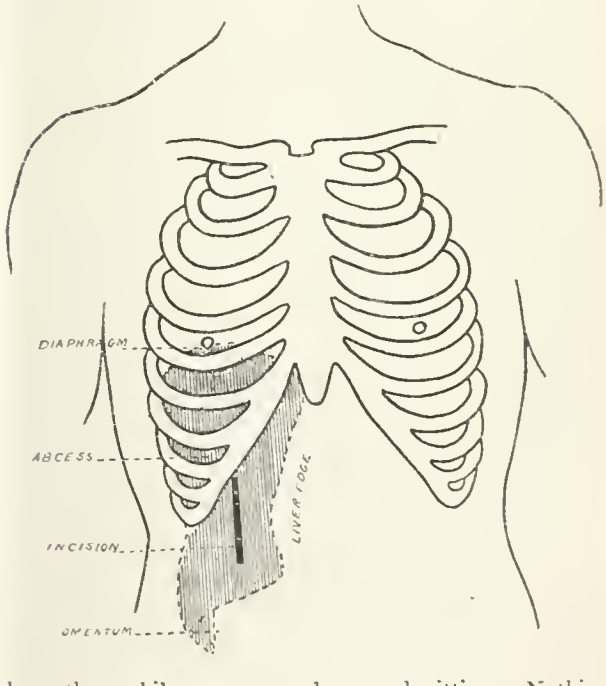
REMARKS ON SUB-DIAPHRAGMATIC AND RECTAL ABSCESSES OF APPENDICAL ORIGIN.[1]

BY ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, ETC.

MUCH thought has been given of late years to the subject of appendicitis, and a large experience has already been gathered in aid of the proper treatment of this disease. Much, however, remains to be investigated, and points of importance in the natural history of the disease, particularly in the so-called catarrhal form, are yet unsettled. Every surgeon who has had to see, or operate on, many of these cases appreciates, however, to a very strong degree the irregularities and variations that may present themselves in any given instance. Hence for one reason the great interest this department of surgery has for an operator. He feels that his highest skill may be called for at any moment He has learned that the apparently late-forming tumor, which seemingly has glued itself to the abdominal parietes, and which presents itself at first sight as an abscess in a safe condition for a simple incision, cannot always be easily differentiated from a deeper abscess that may require the opening of the general peritoneal cavity in order to reach it. He knows, too, that many an abscess of like origin, especially if its opening is postponed beyond a week's time, or if the local symptoms have progressed with rapidity (I refer chiefly to a decided enlargement of the tumor), may demand the establishment of a lumbar counter-opening in order to effect safe and proper drainage. Unexpectedly, there may happen, among the variations occurring, conditions like those which I beg now to lay before you, in a brief detail of two cases that have come under my charge in the last fortnight. The first case is one where the abscess located itself between the diaphragm and the liver. It was found in the person of a man, aged about fifty, a patient of Dr. Pierson, of Roselle, N. J., from whom the history was obtained that he had had, for several years, attacks of colicky pain of short duration and without jaundice, which were most acutely felt across the epigastrium, and never in the iliac fossa, and without gastric symptoms. Some two weeks before I saw him, that is to say, on November 7th, he was seized with a severe pain in the right iliac region, with vomiting and fever. The acute symptoms, however, subsided under rest and anodynes, and he was considered to be doing fairly well, though kept in bed by weakness. His temperature remained, after the fifth day, generally near the normal, but the tenderness persisted in the cæcal region, and there was inability to urinate, save with the catheter; no tumor was felt there, nor were there any chills. Two days before I was summoned the pain increased in severity and vomiting set in, which persisted and increased in frequency, and it was thought, moreover, to have a fecal odor.

At my examination, November 25th, I found the patient vomiting a bilious green fluid every ten or fifteen minutes, having a rank odor. His temperature was nearly normal, 99° F.; pulse, 130; the facial expression was bad, and he had an occasional hiccough. The abdomen was generally distended, though soft and free from pain on the left side. In the right iliac fossa nothing was to be felt, but by percussion dulness was elicited, running from the liver line some three or four inches below the ribs and extending toward the median line. Above, in the epigastrium, there was a line of resonance reaching outward half-way along the ribs. In the right flank, between the ilium and the ribs, was flatness on percussion, but as tenderness was not here elicited it was doubtful if the abscess cavity extended so far. I was puzzled in outlining the mass, as no edge of a tumor could be plainly made out, even after ether had been administered, and percussion even gave a varied note. With this, there was over the belly of the rectus, just



above the umbilicus, some redness and pitting. Nothing was felt per rectum. The diagnosis ventured on was that there was a sub-hepatic abscess of either appendical origin, or from perforative ulceration of the gall-bladder, or perhaps only a large empyema of the gall bladder itself. His antecedent colicky pains squinted somewhat in the direction of an hepatic origin of the abscess. An incision was accordingly made from the ribs to the umbilicus, along the outer edge of the right rectus muscle. The deeper tissues of the abdominal parietes were found œdematous, and on opening with a small incision the peritoneum, gas in large quantities and pus intolerably fetid but not fecal in odor, were discharged. The fluid was allowed to escape slowly, as the jet showed the great

[1] Presented at the meeting of the Practitioners' Society, held December 4, 1891.

tension of the abscess-walls and its severe pressure on neighboring parts. After a quart of pus had escaped, the opening was enlarged and nearly another quart was evacuated. The finger was then introduced, and subsequently, as this failed to reach the bottom of the abscess, a long abdominal glass irrigator was passed in for exploratory purposes. It reached upward to the right nipple and also to the median line of the thorax, and nearly to the linea alba in the abdomen, and then was swept back to the renal region and downward to the crest of the ilium. The wound in the peritoneum was enlarged upward and downward to the length of the original skin incision, and an inspection of the abscess cavity better secured. It was seen to be a subdiaphragmatic abscess, the interior wall of which was formed above by the liver, which had been crowded inward and backward and below by the thickened omentum, which, by its adhesions, especially near the umbilicus and a little below this point, had shut off the general peritoneal cavity. In crowding toward the iliac fossa, which, it will be remembered, even under ether gave no decided evidence of tumor in that region, a track just large enough to admit the exploring finger was detected, leading evidently to the appendix. A counter-opening of considerable size was made in the lumbar region, and through this two large rubber tubes were introduced, one of which was passed into the track leading to the iliac fossa, and the other to the large abscess cavity. Two other tubes were put in through the anterior opening, one running toward the median line and the other between the liver and diaphragm. A final irrigation of boiled water was made, iodoform gauze packed around tubes, and the anterior wound partially closed. The patient was much exhausted, but by hot rectal stimulant enemata, elevation of the limbs, etc., and general heat, reaction was established after a few hours.

I learned, however, that his exhaustion, after a temporary improvement of twenty-four hours with cessation of vomiting and hiccough, recurred, and that the patient succumbed November 27th. No autopsy.

Sub-diaphragmatic abscesses arising from a perforated or gangrenous appendix have not infrequently been recognized at autopsies, and have been best described by Leyden; but until the publication of Dr. Coupeland's cases in the *British Medical Journal* of March 23, 1889, only ill-directed surgical efforts were made for their relief. Since that time a small number of such cases have been reported, and their frequent origin from appendicitis admitted. In an article "On the Treatment of the So-called Perityphlitic Abscesses"[1] I called attention, some two years ago, in analyzing a hundred autopsies from such abscesses, to the fact that in seven instances there had been found purulent depots of appendical origin running up to and behind the liver. These suppurating tracks I found were in each of these cases entirely within the peritoneal cavity, though Coupeland speaks of such abscesses as though they were to be found outside the peritoneum. This I believe to be an exceptional route, and to be accounted for as are the ordinary extra-peritoneal appendical abscesses, by necrosis destroying the parietal peritoneum and in this way allowing access to the extra-peritoneal planes. This view, which was the cause of much contention on my part in the early discussions on perityphlitis, is now so well established as to need no further discussion, except in such a special case as has been presented.

The route by which the abscess reached the liver in this case is, I believe, the one that will be most frequently encountered. It is true that in the autopsies referred to the pus had travelled along the right dorsal gutter to reach up behind the liver, but it will be remembered, in reference to this point, that about a year ago it was my opportunity to present to this Society four cases of abscesses from perforation of the gall-bladder which had pursued a course between the parietal peritoneum and the omenteum downward to the iliac fossa, where they simulated an appendicitis. Another circumstance which surgeons familiar with abscesses originating in the appendix will corroborate, is that not infrequently purulent collections of this latter character will be found, either by reason of a short omentum or from perforation of the omentum, to be situated outside the apron, that is to say, between it and the parietes. In this way, if adhesions are insufficient to bar its progress, the pus may work its way upward as described. I would like here to refer to another point. In the treatment of this very large abscess occurred an incident which strongly confirms me in my long-acquired disbelief in the alleged usefulness of the aspirator needle. As I was about to make my incision it was suggested that aspiration be first made. Now, I am loath to use the instrument, as its negative results often suggest surgical delay, and its chance of help in cases where help is most needed, as in small collections of pus, and where other symptoms are sufficiently present to determine a course of action, is a very slight one. In fact, my only reason for its employment is not as an aid to diagnosis, but as a means to convince a timid or doubting practitioner, or the family of the patient, that pus actually exists in the tumefaction that may be in question. I made in this case a puncture and drew only blood. The subsequent operation revealed I had crossed a thin portion of the abscess and had plunged into the liver, and yet two quarts of pus were present. The withdrawal of the needle was too quick to permit pus enough to appear to show in the blood already aspirated.

The second case which I wish to bring to your notice is one where the abscess not only extended from the iliac fossa to the under-surface of the liver, but also by a separate formation projected toward the rectum, where, by an additional incision, it was opened and drained. Rectal abscesses of appendical origin are not common. Pepper and Lange have already urged, and justly, the necessity of a rectal examination in all cases of appendicitis, and this applies particularly to its late stages. The latter surgeon has, moreover, presented several cases where the abscess was successfully treated by the rectal incision only. Its rarity is shown by the fact of this being the first time in which it has occurred to me in a somewhat large number of abscesses originating in the right iliac fossa. And in this case, indeed, I was nearly misled, for though thought of when beginning the operation, I purposely refrained from exploring the rectum, not only to preserve my fingers aseptic, but also because from its non-occurrence in my other cases, I considered it improbable to be present in this one, and it was only at the end of the operation work in the abdominal parietes that it was felt that the surgical rule should be complied with to render the cure complete. The nearness to error only confirms the value of the rectal examination in all cases.

The history of the case is as follows:

A boy, aged thirteen, was admitted to the New York Hospital, November 28, 1891, with the history furnished by his physician, Dr. Nammack—who had vainly urged earlier interference—that he had been seized for the first time with right iliac pain with vomiting on November 21st. Until sent to the hospital he had grown steadily worse, and though the vomiting had ceased his fever and prostration had continued. When examined by the house surgeon his temperature was 102½° F., pulse, 120. The right side of the belly was so tender as to preclude much handling. He was sent to the operating-room, the surgical clinic being then pending. I found his abdomen distended, markedly so on right side, with a very tense, tender right rectus muscle which did not soften under anæsthesia; and though considerable resistance to pressure was felt all along this muscle and to its outer side, yet no distinct tumor could be recognized. The left side of the abdomen, though tympanitic, was comparatively painless. Percussion was resonant over the whole surface. A slight flatness of note was noticed over the bladder. An incision three inches in length along the outer border of the right rectus muscle was made, running from the umbilicus downward, and as the somewhat thickened peritoneum was opened

[1] On the Treatment of the So-called Perityphlitic Abscesses, Medical News, April 27, 1889.

a gush of foul gas and fetid pus—the latter amounting to about twelve ounces—took place. The wound was opened its full extent, when the cæcum, covered by lymph, was forced into the incision. The finger introduced showed this portion of the intestines to be adherent to the parietes mesially. Downward toward the appendix ran a track of limited length, and upward toward the ends of the floating ribs was found a narrow channel, which was ascertained to lead into an abscess cavity of considerable size, and which was bounded above by the under-surface of the liver, and which ran some distance toward the median line and also passed well posteriorly. A long forceps was crowded backward forcibly enough, with a boring motion, to cause it to emerge beneath the skin just below the middle of the twelfth rib. It was cut down upon from without until the end of the forceps emerged. A rubber tube of large size was then drawn through from behind forward, so as to thoroughly drain the cavity. Irrigation with boiled water was then made, another drainage-tube carried upward and inward toward the liver, and a third toward the iliac fossa. The appendix was not seen and no attempt was made, for obvious reasons, to excise it. The central portion of the wound was carefully closed by silk sutures and the antiseptic dressings applied.

In order to complete the proper routine in abscesses of appendical origin, a rectal examination was then made, and the rare condition of a projecting abscess into the lumen of the rectum anteriorly was recognized. The anus was stretched to allow of ready access to the swelling for its proper incision, and also to permit afterward the ready escape of fluids from the rectum. By a double-bladed rectal speculum the abscess was exposed and an incision with a long, straight knife made into its cavity through the rectal wall, some three inches from the anus and on its right anterior aspect. Nearly eight ounces of pus and gas escaped through the opening. Into it was passed a rubber drainage-tube which emerged from the anus. Irrigation with boiled water was made with moderate pressure only. None of the fluids passed into the cavity of the abscess, however, escaped from the abdominal wound, which had been uncovered to test this point. In other words, this rectal collection was probably a separate abscess, though all had the common origin in the appendix lesion. The rectum about the tube, as it passed into the abscess, was packed with iodoform gauze, and a large antiseptic dressing applied over the anus. Creolin gauze was here used, as bichloride applications so often irritate about the anus and scrotum.

The little patient has made an uninterrupted progress toward recovery. The rectal abscess has been washed out daily with a weak peroxide of hydrogen solution, and his bowels were kept constipated for several days by the use of morphine in small doses.

The final remark may be made that it is not always necessary to open the rectal abscess. In a few instances where the complication has been reported the usual opening in the iliac fossa for the tumor there felt has sufficed to empty also the rectal collection. On the other hand, the opening in the rectum has alone been resorted to by Dr. Lange. Had my patient's condition warranted the prolongation of surgical interference, I should have tried, by a perineal incision, to separate the rectum from the bladder and establish the required drainage exterior to the bowel, and thus avoid the rectal opening. Theoretically, we had better avoid opening into an abscess from the rectum, but time must show whether the clinical disadvantages of so doing are as great as supposed. In this case it was of no detriment.

Foot-warmers.—Boxes filled with sodium acetate are used in the French railway carriages as heat producers. They are filled with the salt in a solid state, which is liquefied by putting the boxes in hot water, and during the five or six hours that it takes to solidify give out heat steadily.

THE CAUSTIC TREATMENT OF CANCER.[1]

By DANIEL LEWIS, M.D.,

SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL.

It is possible that pathological research may yet result in the discovery of an internal remedy for cancer, but an existing malignant tumor can never be entirely removed from living tissue without some active intervention by the physician or surgeon. We lay down the axiom, then, that cancer must not only be destroyed before a cure can be effected, but also in some way removed from the body to insure continued immunity from the disease.

Removal may be accomplished by operation or by escharotics. Up to the present time the tendency of the profession has been toward the surgical operation, to the exclusion of all other remedies which we have been pleased to denominate "quack remedies."

The truth of the matter is, that the surgeon who condemns the caustic treatment *in toto* is just as irrational in his judgment as the cancer quack who declares that all cancer can be cured without the knife, and by a painless process. Both parties are in error, and it is my purpose briefly to indicate the cases which are suitable for caustic treatment, and to describe the means employed. This paper is based upon three hundred cases occurring in my service in the New York Skin and Cancer Hospital and in private practice.

In this report no record is made of the treatment by mild cauterization, which I have heretofore condemned in a paper read before the New York Dermatological Society, and given what appeared to me a justification of the position. Among those which may be termed mild caustics are nitrate of silver, carbolic acid, pyrogallic acid, resorcin, and that South American extract of something which is called alveloz. None of the remedies of this class are true escharotics, but rather irritants. All fall far short of the one great requirement of a proper escharotic for cancer, viz., an agent which will produce rapid as well as complete destruction of the diseased tissue. All are liable to stimulate absorbents and so promote dissemination of the disease, and the only safe employment of them consists in discarding them altogether.

For the purpose of this discussion the following division of cancer may be adopted: 1. Cancer of the breast (including carcinoma and sarcoma); tumors of the axillary and cervical glands; cancer of the vulva, of the testis, of the penis, and of the rectum. 2. Cancer of the cervical portion of the uterus, of the tongue, and of the tonsil. 3. Cutaneous cancer, including cancer of the lip and of the external ear.

All malignant diseases not included under these three heads are outside the province of this paper, as no advocate of treatment by caustics, however ardent his preferences, has ever attempted to employ such means in the treatment of disease of internal organs, of bone, of the thyroid gland, or even of the larynx or vagina, without regretting it afterward.

Before considering these classes in detail, it may be stated that no method of treatment should be employed which aims at anything short of complete destruction and removal of diseased tissue. The only possible exceptions to this rule are occasional instances in which a tongue may be removed to allow of increased facility in feeding, a tumor near the eye where the sight may be preserved, or where a pendulous or ulcerating tumor (as of the breast) may be rendered less painful or offensive for the time being by the removal of a portion of it. Such are palliative measures which may be justifiable, although life is not usually prolonged thereby.

The treatment of cancer of breast by caustics has often been recommended, even by physicians of good repute, while the cancer quack has, almost from time immemorial, secured both fortune and glowing testimonials of merit from this unfortunate class of patients. If the his-

[1] Read before the Medical Society of the County of New York, January 23, 1892.

tory of removal by operation of recurrent disease in my service at the hospital in such cases could be published, with the original testimonials of cure without the knife, it would prove an effective antidote for such insinuating and dangerous pretensions. I hazard the statement that no cancerous tumor of the mammary gland ever existed which was a proper case for the employment of caustic treatment. I do not deny that the tumor can be destroyed and removed by such applications as Marsden's paste, or Bougard's or Michel's paste (I have employed these means successfully), but the process requires several months, is painful in the extreme, crude in its execution, and, worse than all else, tends directly, through the chronic irritation of adjoining tissues, to disseminate the disease to other organs. Of the very small proportion where a cure has finally resulted from these procedures, a much more rapid and satisfactory result would have been secured by a surgical operation. No cancer of the breast should ever be treated without removing every lymphatic gland in the axilla of the side affected, and this cannot be accomplished by a plaster or a caustic of any description.

Mr. Charles Egerton Jennings, of London, in his admirable book on "Cancer and Its Complications," in speaking of cancer of the breast, uses these words: "When caustics are employed to destroy a cancerous growth of any considerable dimensions the results are far inferior to excision or amputation under modern conditions. The bulk of the growth is hardly ever eradicated, and manifest local recurrence occurs ordinarily after the lapse of a few weeks. The caustics are applied and reapplied, and this sad treatment goes on until the patient is relieved by death of a treatment which adds pain to that of the disease, which it ordinarily aggravates."

He makes an exception in favor of caustics in certain very old and debilitated patients, where there is an open ulcer, with the surrounding tissues adherent to the ribs, for the purpose of arresting offensive discharges for a while, and ends by recommending a preparation consisting of

℞. Hydrochlorate of cocaine	2	grammes.
Caustic potash	6	"
Vaseline	8	"

After the skin is well cleansed, small portions of this paste are well rubbed in with a wooden spatula, and in a few minutes considerable tissue can be destroyed. It is not a painful application, and I have removed small growths on various parts of the body quite satisfactorily. The charred portions should be carefully wiped away with absorbent cotton during the application, to prevent destruction of adjoining healthy tissues.

Whatever arguments can be urged against caustics in breast cancer apply with increased force to disease in the axillary glands. The cicatrix resulting from such treatment resembles that of an ordinary burn, and not long since a patient applied to me after a tumor of the axilla had been removed by a celebrated "dealer in knifeless operations," and the contraction had firmly bound the arm to the side. I may add that the disease recurred in the cicatrix.

In the glands of the neck there is the added danger of destroying important organs, for only great familiarity with any caustic can enable us to predict the extent of its action to the requisite degree for the safety of the jugular vein or the facial artery. The instances of this class where caustics have been employed that have come under my notice are sad beyond description, and the only word to add concerning caustics in tumors of the neck is the most sweeping condemnation. The same may be said of tumors of the testis, which are likely to be cancerous and of rapid growth.

A small superficial tumor of the vulva may sometimes be removed by electrolysis or the Paquelin cautery, but my own experience and observation in these cases compel me to state that recurrence is usually rapid and certain, and the only reasonable hope of cure lies in an early and free excision. No time should be lost in the attempt to cure with caustics.

Dr. C. W. Allen recently presented to the New York Dermatological Society a patient with epithelioma of the glans penis where Bougard's paste had been employed successfully, but the corpus spongiosum is so excessively prone to infiltration with cancer that amputation as near the pubis as possible appears the safer procedure. A radical cure of the penis by operation is not unusual, provided treatment is undertaken early in the progress of the disease. The caustic paste may be considered admissible provided the disease is confined to a small portion of the foreskin, if indeed that condition is ever met with in practice.

Of our second class—cancer of the cervical portion of the uterus, of the tongue and the tonsil—it will be noted that they are in a class by themselves, because the plasters, pastes, etc., cannot be used without poisoning the patient, and some form of the actual cautery is the only proper escharotic, should any be deemed advisable.

In regard to the cervix there is so much to be said that the limits of this paper forbid a thorough discussion of the subject. I believe, however, that of the considerable number of cases which I have observed in my own and my colleagues' practice, all are now dead with one exception, and she is not likely to long continue to break this dismal record of mortality. Many have been curetted thoroughly and afterward cauterized, and some arrests of symptoms secured, but all improvement was only temporary. Mr. John Williams gives his cases in admirable detail, and high amputation was no more satisfactory. Extirpation, in the cases where the woman survives the shock, is sometimes followed by recurrence in the peri-uterine cellular tissue, so that we are forced to the conclusion that cancer of the uterus is one of the most incurable of all the malignant diseases.

The spongy character of the tongue accounts for the extreme malignancy of disease therein and its consequent incurability. Even the actual cautery is useless, and whether you amputate by Whitehead's or Kocher's method, or any other, a year of immunity is longer than I have ever secured, although Butlin reports six cases out of a total of seventy who remained cured after three years.

It may be said, in brief, concerning epithelioma of the tonsil (primary), that the removal thereof by cautery involves great danger from secondary hemorrhage, while primary hemorrhage is very liable to cause death when removal by operation is attempted, so that the only favorable comment to be made upon these cases is the extreme rarity of the disease, the entire number of recorded cases being less than one hundred.

Concerning the third class, which comprises all cutaneous cancer, epithelioma of the lips and of the external ear, it may be said that they are the most curable of all varieties of cancer, and in this respect stand in sharp contrast with the class just considered. There is no reason why ninety five per cent. should not be absolutely cured, if treated at the earliest period in the course of the disease. There need be no hesitation in giving the patient himself this prognosis, provided always that he will permit very frequent observation and prompt destruction of any epithelial growth.

Cutaneous cancer is usually treated more satisfactorily by escharotics than by any other method, and for various reasons. The patients are usually past middle age, and often far advanced in years, and, as a class, not good subjects for etherization. The antipathy to a surgical operation often leads them to delay treatment until the precancerous stage, as Mr. Jonathan Hutchinson has termed it, has been followed by one of active malignancy. You can always quite readily persuade them to have a plaster applied. The disease can be thoroughly destroyed by the caustic plasters, for they will all act sufficiently upon diseased tissue in so much less time than upon healthy skin that there is almost an excuse for the fallacy that they exercise a positive power of selection. The resulting

cicatrix, when the deep subcutaneous tissues are not involved, is a very smooth, white, and in every way healthy one, far less conspicuous than after operation. The only cases in which an operation should be preferred to a caustic are those involving the mucous surface of the lip, the eyelids, and all others which have involved a large surface, so that dangerous poisoning might result from absorption.

The choice of a proper escharotic is of considerable importance. If the disease be a very small warty growth, the potassa and cocaine paste of Mr. Jennings is a good one. Acetic acid must be at hand to limit its action as soon as desired. Where the disease is that form of epithelioma called rodent ulcer by some, and Jacob's ulcer by other authors, with little or no induration of the borders, a paste composed of lactic acid and silicic acid, in such proportions as to make a thick paste, is effectual in destroying the diseased surface. It has one advantage over others in that it is not poisonous, and can be spread over a large surface. It is less active than the others, and requires frequent repetition. I now very seldom employ it. The actual cautery is too painful, and patients are much frightened by the very appearance of the doctor armed with a red-hot instrument.

In 1874, in a paper before this Society, I described the method, then new, of applying an arsenical paste as recommended by Dr. Alexander Marsden, Surgeon-in-Chief of the London Cancer Hospital, and gave histories of 12 cases successfully treated by it. Since that time I have employed the same paste in over 100 cases. It is satisfactory in the main, and has become a well-recognized remedy throughout this country. In some cases the reaction is very great and the pain very severe, although less pain is experienced if cocaine is mixed with it. It is composed of arsenious paste, two parts; mucilage of acacia, one part; mix into a paste too thick to run. It is then applied to only one square inch of the ulcer, covered with cotton to absorb any superfluous paste, and left on until swelling occurs around it, with heat and redness, when it is removed and a line of demarcation usually surrounds the surface cauterized. From one to three days are required to produce the desired effect. Warm poultices are then applied until the slough separates (usually about a week), when, if the disease is all removed, the healing process proceeds as in an ordinary granulating sore. The same process is to be repeated until the disease is all removed. Marsden insists that no cancer of more than four inches in extent should be thus treated, and only one square inch at a time, and the case very carefully watched. The surgeons of the London Hospital inform me that even Marsden himself seldom employs the paste. They have substituted an application called Bougard's paste, after the Belgian surgeon who first published the formula in his work on caustics. This author brought it forward as a cure for mammary cancer, but as such, in my judgment, it is open to the same objection as all other caustics; but in cutaneous and lip cases, in fact all surface epitheliomata, where any escharotic is admissible, this is by all odds the best we have at present. It is less painful than Marsden's, forms a more dry and friable slough, can be safely applied to a larger surface, and can always be prepared and ready for instant use, for in a covered jar it will keep for many months. With both pastes the surface must be denuded, if necessary, by caustic potash to render the action prompt and effective in the shortest possible time. Bougard's formula is as follows:

Wheat flour	60	grammes
Starch	60	"
Arsenic	1	"
Cinnabar	5	"
Sal ammonia	5	"
Corrosive sublimate	0.50	centigramme.
Solution of chloride of zinc at 52°	245	grammes.

The first six substances are separately ground and reduced to fine powder. They are then mixed in a mortar of glass or china, and the solution of chloride of zinc is slowly poured in while the contents are kept rapidly moved with the pestle so that no lumps shall be formed. A thick layer of this is spread on cotton and left in position twenty-four hours, and then managed in every way as Marsden's paste. Few cases require a second application. The ulcer may be dressed with balsam of Peru ointment of varying strengths, according to the stimulation required, and all exuberant granulations are to be kept in check by the usual methods. An excellent dressing, instead of the Peruvian balsam, is a five or ten per cent. aristol ointment, with vaseline as a base. However, this after-treatment is not of vital importance except in one respect, viz., healing under a scab in cancer cases can never be trusted.

GOUTY EYELIDS. A CASE OF RHEUMATIC IRITIS AND A CASE OF RHEUMATIC KERATO-IRITIS.

By JOHN E. WEEKS, M.D.,

NEW YORK.

In addition to the tophi, met with in the lids of old gouty subjects, which appear as subcutaneous, pale, nodular masses, usually remaining in the tissue without producing any irritation, but sometimes producing suppuration in the surrounding tissue, we have a peculiar form of lid affection which in certain cases is one of the first pronounced signs of the gouty diathesis. This consists of a marked swelling or puffiness of the lids and conjunctiva with more or less chemosia, accompanied by a muco watery discharge, quite annoying to the patient, and of greatest severity whenever there is an exacerbation of gout. The following is an illustrative case:

Mrs. C——, aged thirty-eight. Came on account of a marked swelling of the lids and conjunctiva, and profuse lachrymation. There was a family history of gout. The lady herself had suffered from gout in the ankle and toe-joints, and in other parts of the body for some years. The eyelids are more swollen in the morning than in the afternoon. The swelling is greatest and most troublesome during an exacerbation of the gout. The family physician reports excess of uric acid in the urine, no sugar, no albumen. The condition of the eyes when seen was as follows: Lower lids very œdematous, pale, translucent; the upper lids partake of the same condition to a less degree. Conjunctiva swollen and pale; the ocular as well as the palpebral conjunctiva being affected, there was some chemosis present. There was quite a profuse watery discharge, some photophobia, and considerable discomfort. Alkaline waters and colchicum were ordered and rapid improvement followed their use.

I have seen the patient at intervals and learn that her lids give her trouble whenever she has an acute attack of gout.

In connection with this peculiar swelling of the lids we not infrequently see a roughening, a mild form of eczema of the integument of the lids, accompanying gout.

A gentleman, a sufferer from gout, who has been under my observation for some years has this form of lid affection. The urine shows excess of uric acid and water; no albumin, no sugar. The condition of the lids grows worse or improves, according as the manifestations of gout in other parts of the body are pronounced or imperceptible. The condition of the lids is a true indication of his general condition so far as the gout is concerned. An ointment of the yellow oxide of mercury applied to the lids controls the eczema, but constitutional treatment directed to the gouty diathesis is required to cause a subsidence in the œdematous swelling.

Rheumatism, acute or subacute, as a cause of iritis is probably not the most common; however, it stands in a causative relation in a large number of cases, and presents a large range in form and in severity. The serous, spongy, and plastic varieties, the "quiet" or painless

iritis of J. Hutchinson, and the acute or intensely painful forms are met with.

The two following cases are illustrative of the "quiet" and of the acute forms of plastic, rheumatic iritis.

Case I.—Jennie J——, aged twenty-two, came to the New York Eye and Ear Infirmary, Dr. Derby's service, December 23, 1890, with iritis of the left eye. The patient has been "troubled with rheumatism since childhood." She has had two severe attacks of inflammatory rheumatism within the last eighteen months. There was no history of syphilis. At present the patient appears to be well-nourished and the general health is good. The patient first noticed "a little redness of the left eye" and some dimness of vision during the last week of August, 1890. She has never had any pain of any consequence in the eye, or in the left side of the head. The surgeons at two dispensaries have been consulted who have prescribed mercury, potassium, and atropine. According to the patient's statement the vision has grown gradually worse.

Present condition: Slight pericorneal injection in the left eye, almost complete posterior synechiæ. A thin membrane fills the pupillary space, preventing any but the faintest reflex from the interior on ophthalmoscopic examination. Globe slightly harder than normal. After atropine had been instilled the vision = $\frac{6}{200}$, not improved with glasses. There was no pain in or about the eye. Treatment, salicylate of soda, gr. xij., every three hours, atropine one per cent. instilled into the eye four times daily. Hot applications.

December 29th.—Pericorneal injection less in amount. Some of the filiform iritic adhesions broken. Pupil irregularly dilated; tension normal; vision = $\frac{2}{70}$.

January 18th.—Eye white; quite a number of firm adhesions between iris and lens; capsule remain; tension normal; vision = $\frac{2}{50}$.

Case II.—Gerhardt S——, aged thirty-eight, married; policeman on night duty; has had a number of attacks of inflammatory rheumatism. The patient is a large, powerful man. There is no history of syphilis.

On August 24, 1888, Mr. S—— was compelled to take to his bed on account of a severe attack of inflammatory rheumatism. He was seen by his family physician and put on anti-rheumatic treatment, the salicylates being given in small doses. Pain in and above the right eye was noticed on September 1st. On the advice of his family physician an oculist was consulted who prescribed atropine and the iodide of potash. The patient suffered a great deal from pain, particularly at night. I saw him on September 7th. He was then in bed, and could move only with great difficulty on account of the extreme sensitiveness of the swollen joints. The knee, ankle, and right shoulder joints being the ones most involved. The temperature was 103° F. The condition of the right eye was as follows: Intense pericorneal injection. Pupil small. Many posterior synechiæ. Thin layer of exudation in pupillary area.

Cornea the seat of six or eight punctate opacities, some of which were in the parenchyma, three or four were near the surface causing loss of the corneal epithelium at these points; they were not pustular. Great photophobia; tension plus; vision greatly reduced.

Diagnosis.—Rheumatic kerato-iritis.

Treatment.—A one per cent. solution of atropine was instilled every two hours. Room darkened. The salicylate of soda, gr. x., was given every two hours. A saturated solution of the iodide of potash, gtts. xii., three times a day after meals. Five leeches were applied to the temple at night and the after-bleeding was encouraged by making warm applications. The pain in the head was so severe that morphine powders (gr. $\frac{1}{4}$) were left. Of these he took three during the night.

There was some improvement in the appearance of the eye after twenty-four hours. The pain after this rapidly subsided. A solution of the bichloride of mercury, 1 to 8,000, was employed to instill into the eye three times daily. Five days later the patient was able to sit up. The fever had abated, the pericorneal injection had markedly decreased and the corneal epithelium had become replaced, the deep-seated corneal opacities were still visible. The case progressed slowly toward recovery. October 20th, the patient returned to his post; at this time the cornea was clear. A number of posterior synechiæ remained, and there were some remnants of membrane in the pupil; vision = $\frac{20}{100}$. The salicylate of soda was continued for a week or ten days, when all pains of a rheumatic nature had disappeared.

February 6, 1889.—I was again called to see the patient. After a severe exposure to inclement weather he had experienced some joint pains, and two days before calling me the left eye had become red. When seen by me there was some pericorneal injection and a mild form of plastic iritis. As there was considerable pain in the temple, five leeches were applied. Atropine was instilled into the eye, and the salicylate of soda in frequently repeated doses was given internally. The pupil dilated irregularly on account of some filiform posterior adhesions. These were broken up and the patient recovered so that he resumed work in twelve days' time. Cornea clear.

On May 26, 1890, this patient suffered from a recurrence of plastic iritis in the right eye, with some punctate opacities in the cornea. Leeches, atropine, and the salicylate of soda were employed. This attack came on after exposure and was accompanied with rheumatic pains in the joints of the lower extremities, some swelling and some fever. In two and one-half weeks the patient was again ready to report for duty. A few filiform adhesions still remained in the right eye. Vision = $\frac{20}{30}$ in the right, and $\frac{20}{40}$ in the left eye.

Since May of 1890 there has been no relapse. The above appears to be a case of kerato-iritis of purely rheumatic origin. Syphilis and gonorrhœa were excluded.

154 Madison Avenue.

PYORRHŒA ALVEOLARIS, OFTEN DIAGNOSED AS FACIAL NEURALGIA.

By CHARLES G. PEASE, M.D., D.D.S.,

NEW YORK.

I have been induced to write this article for the benefit of my brother general practitioners, owing to the number of cases of pyorrhœa alveolaris accidentally and otherwise falling into my hands, which have been previously diagnosed as facial neuralgia and treated for such, of course, without success. It might be well here to consider the pathology and etiology of this disease of the oral cavity. It has been maintained by some that it was of local origin, while others have ascribed it to constitutional causes. Although it is a disease depending almost wholly upon local causes, such as the irritation produced by a salivary and sanguinary calculus—the latter always a resultant of degenerative conditions of mucous crypts surrounding the necks of teeth, insoluble dentifrices, denture clasps, caustic agents, etc.—yet its peculiar manifestations no doubt often depend upon some unfavorable diathesis which enables the local causes to produce more serious effects than might be possible in better systemic conditions. Mercurial medicines should not be forgotten as a cause. The constant irritation produced by salivary calculus, or by other irritants at the necks of teeth, produces an inflammation of the gingivæ, causing them to weep a serous fluid, from which we get the serumal deposit upon the tooth under the free margin of the gum, this acting as an additional irritant. Simple gingivitis will in this way contribute to the development of the disease. When a slight deposit has taken place it becomes an irritant which will in itself perpetuate the disease. The gum and lower border of the peridental membrane is kept in a state of chronic inflammation, resulting in the continued though very slow increase of the deposit. It may be years before it will be productive of

serious conditions. Finally, ulceration of the peridental membrane occurs and is gradually destroyed. The alveolar wall is absorbed, and a pocket is formed between the root of the tooth and the gum. The serumal calculus is deposited as the root is denuded of the peridental membrane, and so continues in the work of destruction to the very apex of the root, the tooth becomes loose, pus exudes about the neck of the tooth, and the dental organ is finally lost.

During the progress of the disease there are frequently periods of considerable pain, often lasting for weeks or months, simulating facial neuralgia, frequently augmented by food in the pockets undergoing fermentation about the necks of the teeth, making them acutely sensitive. These conditions are too frequently overlooked by the dental surgeon, a large number of cases giving no visual evidence to the unpractised eye of the progressive disease which will finally prove so disastrous, if not properly treated. I will cite several cases.

Miss B——, aged twenty-four, came to my office to consult me upon the subject of her sufferings. She had been treated for neuralgia of the face; her own dentist, whom she had consulted for caries of the teeth as a possible cause of the trouble, could not find anything in the condition of her mouth indicating a cause, but gave her the comforting assurance that the neuralgia would soon pass away and that he could do nothing for her. She bore the pain for months, it was constantly increasing, and she was not able to rest at night.

On examination I found the condition of which I am superficially treating in this article, over two of her teeth, left superior six and twelve year molars. By the means of appropriate instruments I removed the accumulation of serumal calculus (hidden from view) to the full extent of the pockets, together with the fermenting food, etc., as well as I could at one sitting. I then applied indicated remedies and made an appointment for another sitting, telling her that I had no doubt of her being able to sleep that night, which prediction she realized with so much pleasure that she could not wait until the next appointment but wrote me the following morning telling of the complete success of the operation.

Mrs W——, aged forty-four, brought to me by her physician, had been treated unsuccessfully for facial neuralgia. Her own dentist could not find anything about her mouth as a cause. On examination the same conditions presented about six of her teeth, the gums being badly congested, to all of which I called the attention of her physician. She was placed under my care for the local trouble. The pain diminished markedly under treatment, and entirely disappeared in several days, the tissues returned to their normal condition, and in three weeks the pockets were completely closed.

Mr. S——, aged forty-two, was suffering from one of his frequent attacks of so-called facial neuralgia. I found the majority of the teeth involved, at some points the disease had progressed to a serious degree. He was much surprised when I told him the cause of his trouble, demonstrating it by affording relief. He made the statement that his sister had suffered with the same character of pain, and that, after being treated for facial neuralgia without relief, she had had a number of sound teeth extracted, not knowing what else to do. It will be borne in mind that the tooth itself may be perfectly sound. These cases are but a type of many. If the diagnostician will think to look for this disease as a possible cause in symptoms of facial neuralgia, it may clear up a large number of cases.

101 West Seventy-Second Street.

Enemies of Tobacco Smoking.—The ladies of St. Petersburg have organized associations of men and women with this title, the members of which have pledged themselves not to smoke, and to give the money thus saved to the famine sufferers.

Progress of Medical Science.

Duodenal Indigestion.—Dr. Allchin says in his Bradshaw Lecture (*Lancet*, December 5–12, 1891): Owing to the different nature of the alimentary principles and the corresponding different nature of the means for digesting them, they are not all reduced to a fluid and absorptive state at once, but at successive parts of the canal. Thus we have buccal, gastric, and intestinal indigestion. Of the three groups of alimentary principles — proteids, carbo-hydrates, and fats—the first require the greatest amount of digestion, and in the stomach are mostly converted into diffusible peptones. Up to the passage of the chyme into the duodenum, the fats have been untouched. The chyme appears as a gray grumous fluid of strongly alkaline reaction, and consists of such proteids and carbo-hydrates as may have escaped any action by the gastric juice and saliva, unabsorbed salts and water, indigestible substances, remnants of saliva, and a variable quantity of gastric juice. What is termed duodenal digestion is the action upon the chyme of the bile and pancreatic juice. It takes place throughout an unknown length of the duodenum, and consists in a special preparation of the fats for absorption, and a supplementary treatment of the carbo-hydrates and proteids. The pancreatic digestion of proteids is, however, carried further in the disintegration of the molecules than the gastric digestion is, since the hemi-peptones of tryptic fermentation may be converted into leucin and tyrosin, preliminary stages to the excretion of the nitrogenous excess as urea. The conversion of undigested starches of the chyme of the amylotic ferment of the pancreatic juice is exactly comparable to the action of the ptyalin of the saliva. In the alkaline contents of the intestine various micro-organisms find a suitable field for activity, but so far as is at present known, the entire process of digestion would be equally well carried on in the complete absence of these organisms. The following is quoted from Halliburton: "A useful function fulfilled by the organisms appears to be the destruction of poisonous substances, such as cholin, the alkaloid derived from lecithin. It is possible that, if other alkaloids (leucomaines) are formed by the processes occurring in the intestines, these also are destroyed, for they are absent in the normal excretions." The author insists on the all-importance of salivary and peptic digestion of food, before the bile and pancreatic juices are called upon to exercise their activity.

The conditions leading to intestinal indigestion are thus summarized: 1. Some impropriety in quantity or composition of the chyme, including initial errors in diet. 2. Some perversion in the quantity or quality of the bile and pancreatic juice, more particularly the latter. 3. Some accessory fermentation process or processes of an abnormal character. 4. Exaggerated or deficient peristalsis. 5. Defective absorption of the digesta. Any form of duodenal dyspepsia must be directly referable to one or other of these causes. Excess in the quantity of one or more of the required alimentary principles in the great majority of cases directly brings about a dyspepsia. Again, the author finds that chyme containing a large excess of proteid matter gives the opportunity for increased activity and development of the intestinal micro-organisms which are ever ready to assert their power, and the decomposition effected by the living germs becomes more and more putrefactive and leads to the production of many toxic substances, leucomaines, etc. These becoming absorbed, are largely responsible for remote symptoms of dyspepsia. The author believes that putrefactive changes are mainly effected low down in the canal, are not much influenced by the bile, and he is unaware of any control being exercised by this fluid over those toxic substances which may be formed from the decomposition of the proteids.

In regard to symptoms by which we can discriminate

mal-digestion in the intestine from that in the stomach, we have local manifestations and those which are remote from the digestive organs. Among the local symptoms of indigestion are included: 1. Pain and all other sensory perversions, varying from a mere sense of weight at the epigastrium to acute, griping colic, or sensations of a peculiar character, such as heartburn. 2. Evidences of perverted peristalsis, such as diarrhœa, constipation, vomiting, with all varieties of ejecta from unaltered food to blood, bile, clear acid fluid, or yeasty fermenting material. 3. Signs of undue distention of parts of the canal, flatulence, and meteorism, causing general abdominal fulness. 4. State of the tongue and mouth; salivation. 5. Character of the evacuations. Among the remote symptoms are pain, headache, various neuralgias, lassitude, cramps, especially in the calf, flushings, cold extremities, palpitation, cardiac irregularities, fainting, angina, skin eruptions, abnormal urine, etc. The time of the appearance of local symptoms after taking food does not warrant us in attributing them to either the stomach or intestines, nor are there among the local symptoms any which might be termed diagnostic of the situation, nor can such irregularities as constipation or diarrhœa determine the existence of a gastric rather than a duodenal indigestion. Acidity, heartburn, and pyrosis, while undoubtedly pointing to stomach indigestion, do not of necessity exclude a coexistent duodenal failure. Nausea and vomiting may be due to causes quite remote from the digestive organs, still both may result from absorption of toxic intestinal digesta. Probably most gas of an ill-smelling character which is eructated originally comes from the intestine. Flatus is accounted as evidence of mal-digestion in the intestine, where sulphuretted hydrogen and marsh-gas may be looked upon as exclusively developed, and intestinal flatulence is probably the most reliable local sign of duodenal dyspepsia, owing its origin to excessive ferment action of micro-organisms. Symptoms ordinarily described as "dyspeptic" are noticeably absent where normal duodenal digestion is rendered impossible through an absence of bile and pancreatic secretions in certain cases, and this is regarded as a clinical fact of great significance. In conclusion, the author thinks the most important factor of duodenal dyspepsia is its dependence on abnormal fermentation, caused by micro-organisms introduced *ab extra*.

Salicylate of Soda in Pleuritic Exudation.—Dr. Oerl has, during the past five years, treated nine similar cases of pleuritic effusion with salicylate of soda, after other remedies, such as phenacetin, pilocarpine, etc., had failed, and with the exception of two instances the results were favorable. In these two the resorption was only partial. The author concludes: 1. Serous pleuritic exudations of long standing may be removed by the administration of the salicylate of soda. 2. The salicylate has in exudative pleuritis, just as in polyarthritis, an apparently specific effect. 3. The fact that, so far as experience with this remedy has gone, no new collection of fluid is observed, makes surgical interference in serous pleuritic exudation not only not imperative, but, indeed, puts operative procedures in the background.—*Medizinal Zeitung*, No. 98, 1891.

Exalgine.—From a study of the analgesic properties of exalgine made by Dr. Désiré, at the Hôpital Lariboisière, the conclusion was drawn that, aside from any antithermic action, the product is an admirable specific against pain. It was employed in a great variety of apyretical affections with uniform success. The dose of twenty-five centigrammes, or about four grains, was found sufficient for most cases, but it can be pushed to double or treble this quantity, though as much as a grain is scarcely ever necessary. If medicine rarely cures, it should at least always console, and sometimes relieve, and with exalgine the author thinks great relief can often be given.

Clinical Department.

TWO CASES OF PURULENT RHINAL DISCHARGE.

By FRANK L. STILLMAN, M.D.,

COLUMBUS, O.

The two following cases are reported together—first, to contrast the diagnostic points of the two diseases; second, because of a slight originality in the treatment of the first, and to illustrate the ready improvement in an uncomplicated case of this kind when treated antiseptically; third, to illustrate the difficulty of bringing about a cure in the second case, owing to the chronicity and inaccessibility of the inflammation.

Case I.—Mrs. X——, aged forty; occupation, housewife; temperament, nervo-lymphatic; hair, golden-brown; eyes, blue. Has had no children, general health has been fairly good until two years ago, when she had necrosis of one of the upper dorsal vertebræ, which was cured by the plaster-of-Paris jacket, under the care of Dr. J. F. Baldwin.

Shortly before her first visit she placed herself in the hands of Dr. Otto Arnold, a dental surgeon, in order to have the second molar tooth on the upper jaw, right side, "capped." The tooth was found to be sensitive, and she complained of pain in the right cheek, and an offensive, purulent discharge from the nose and into the naso-pharynx. She was referred to me for treatment. I advised extraction of the tooth, which was done.

June 16, 1891.—From the nose she has a fœtid discharge, which is seen issuing from under the right middle turbinate, and pus can also be sucked into the mouth through the tooth-socket. In other respects the upper respiratory tract is healthy. As the patient is refined and sensitive, the bad odor and excessive amount of the discharge caused her much distress. The flow is increased by the recumbent posture and by inclination of the head forward or to the left.

Diagnosis.—Empyema of the right antrum of Highmore.

Treatment was begun at once, and consisted in "flushing out" the diseased antrum through the tooth-socket with a warm solution of hydrarg. bichlor., 1 to 5,000. This was done daily. The irrigation was accomplished by means of a reservoir or fountain syringe, which insures much more perfect cleansing than can be done with the piston syringe. The amount of fluid used each time was from a pint to a quart. The artificial opening into the antrum was kept pervious by a drainage-tube, made from a close spiral of silver wire, which was replaced by a new one daily. Cleansing and soothing sprays were also directed to the nasal mucous membrane in order to prevent obstructive swelling around the hiatus under the middle turbinate.

July 8th.—Discharge is diminishing and has nearly lost its offensive odor. Discontinued douche and commenced semi weekly insufflations of boracic acid into the antrum, the powder being blown in from the tooth-socket.

August 1st.—Seems entirely well.

August 8th.— Discontinued treatment and left in a drainage-tube only half an inch long. This was removed in about a week, and the patient has had no return of the discharge.

Case II.—Mrs. Y——, aged sixty; occupation, housewife; temperament, motive; hair, gray; eyes, brown. Mother died of fatty degeneration of the heart at the age of sixty-eight, and father of paralysis at fifty two. She has two brothers and three sisters living—all well. One brother died of phthisis, has two living children. One daughter died at age of eighteen from phthisis, lost three children prematurely. She was taken sick ten years ago with psoas abscess and "change of life;" was confined to bed for many months, but finally had a complete recovery. She dates the present trouble back about a dozen years.

It began gradually as a rhinitis; she now has a flow of purulent matter from the nose and into the pharynx. The discharge has an offensive odor, and is increased in amount by inclining the head forward. The patient says she soils a dozen handkerchiefs daily, and is compelled to clear the passages very frequently. Has a dull, aching sensation between the eyes, and also at the back of the neck and top of the head behind. Besides this she is subject to weekly attacks of typical migraine, with the "fortification outline" of scintillating light, and slight aphasia. With reflected light the mucous membrane has a grayish, sodden appearance. The middle turbinates are somewhat hypertrophied, while there is atrophy of the inferior turbinates and in the pharynx. Upon close inspection the discharge is seen to issue from under the superior and middle turbinated processes on both sides of the nose. The flow takes place when the head is inclined forward, and is not increased by lateral inclination of the head. This last symptom, together with the absence of swelling or pain in the cheek, the bilateral nature of the discharge, and the negative results of electric transillumination exclude empyema of the antrum; and the absence of frontal pain or tenderness indicates the probable absence of inflammation of the frontal sinuses. There is no indication of suppurating pouches. The trouble, then, is probably chronic purulent inflammation of the anterior and posterior ethmoid cells, and possibly also the sphenoid cells.

Treatment was begun August 12, 1891. It consisted in the use of a cleansing and disinfecting spray of potass. permang., gr. j. to ℥ j., followed by a spray of menthol and eucalyptol in albolene. To give as free exit to the discharges as possible trichloracetic acid, and at a later period galvano-cautery punctures of the middle turbinates, were employed. Internally she has been taking elix. iodo. brom. calcium. This treatment was kept up steadily until September 23d with no appreciable diminution of the discharge. Since the treatment began she has been entirely free from one of her bad symptoms, viz., the migraine. This has probably been due to the fact that the nasal passages have been kept measurably clear from the decomposing discharge by the sprays employed. On September 23d, the insufflation of boracic acid was substituted for the menthol and eucalyptol sprays, but in about a week this was replaced by a spray containing aristol. The patient is still under treatment, but any further amelioratiom of her condition does not appear probable.

SALICYLIC INTOXICATION.

By FREDERICK W. MANN, M.D.,

DETROIT, MICH.

RESIDENT PHYSICIAN DETROIT SANITARIUM; SECRETARY SURGICAL SECTION AMERICAN MEDICAL ASSOCIATION, ETC.

The physiological actions of salicylic acid have been so thoroughly worked out in the laboratory, and these have been so generally confirmed by clinical experience, that any extreme deviation from the recognized order of phenomena accompanying the administration of this drug is rare and unusual. The toxic dangers of salicylic acid are usually esteemed to be those due to its action as a cardiac or respiratory depressant, and these are always in the mind of the watchful physician. The toxic effect of the drug on the central nervous system is also a matter of common experience, and numerous observers have reported subacute delirium as a symptom occurring coincidently with its administration. Sometimes well-marked delusions have been noted, and refusal to take food for some cause or other has been a frequent incident of the delirium so produced. It is seldom, however, that anything like acute mania has been known to proceed from the use of this drug, and the case below recorded may, therefore, possess passing interest.

J. K——, a German laboring man, consulted me for an attack of subacute rheumatism. I prescribed a mixture containing two drachms of salicylate of soda in four ounces of peppermint water. Of this mixture the patient was instructed to take a teaspoonful every two hours. In accordance, however, with a belief somewhat prevalent among the Germans, that the more rapidly the remedy is taken the more speedily is the cure effected, the patient proceeded in the course of four hours to empty the entire contents of the vial. As a result of this excessive dose the patient became rapidly hallucinated, manifesting delusions of persecution. A band of Odd Fellows had conspired to kill him. To avoid their persecutions he attempted to escape by the window, and was only restrained by force from committing various acts of violence. During the evening of this day he became so unmanageable that his friends, unable longer to control him, sought aid from the police, the outcome of this being that the patient was incarcerated in a cell for the night. The next morning the patient again came under my observation, and the relatives and police, believing the man insane, questioned the wisdom of confiding him to a physician, and suggested the asylum. In obtaining the history, the ingestion of the excessive dose of the medicine came to notice and the diagnosis of salicylic intoxication was made. The patient was, therefore, allowed to be removed to a hospital. During the next four days the patient manifested all the phenomena of delirium tremens. Visual and auditory hallucinations possessed him. He refused all food, giving as a reason that it would be useless to eat, as he was condemned to be hung. He gazed in a mirror and immediately broke it by striking with his fist the demoniacal image his own reflection suggested. After this he had to be forcibly restrained, and was, therefore, confined to his bed. His attention was incessantly concentrated upon freeing himself from the restraints which had been imposed upon him. When spoken to he responded pleasantly. He was neither coarse in speech nor action; his violence arose solely from the desire to elude his persecutors. His pulse was 130; his respiration was not visibly depressed. At the end of the fifth day the hallucinations gradually waned and disappeared, and the patient rapidly recovered his normal state of health. All trace of rheumatism had disappeared.

Salicylic-acid poisoning is said to be most effectively treated by diuretics. The excretion by the kidney of salicylic acid in the form of salicyluric acid and salicin is the natural safeguard in excessive administration. The occasional occurrence of such cases as the one now recorded lends emphasis to Germain Sée's injunction that salicylic acid should never be administered without a diuretic as an adjuvant.

PHYSOSTIGMA IN HICCOUGH.

Dr. H. M. Shallenberger, of Rochester, Pa, writes: "In a recent issue of the *Edinburgh Medical Journal* Mr. Smart calls attention to a case of obstinate hiccough from chronic alcoholism, so persistent as to prevent sleep and the ingestion of food. No relief followed the use of any drugs, except after the administration of dangerously large doses of morphia persisted in for six days. My object in this note is to assure the profession of the value of physostigma in these cases of obstinate hiccough, from whatever cause. The cases that I have seen have yielded to its influence within two or three days. The last case was precisely like the one reported by Mr. Smart, and forty-eight hours' use of this drug settled the hiccough. Another case of hysterical hiccough, of three months' duration, that had resisted all other agents, was speedily controlled in the same way. A good fluid extract was the form given. The dose is four to eight drops every two or three hours, pushed to the point of causing toxic symptoms."

The Small-bore Rifle will have a tendency, according to Billroth, to shorten war, since a bullet from it will go through several men at a time.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, February 13, 1892.

THE PAN-AMERICAN MEDICAL CONGRESS AND THE ROME MEETING.

THE fact that the Pan-American and the International Congresses are to meet in the same year, and both of them in the autumn, has given rise to the impression among some that the former was conceived in opposition to the latter. Nothing, we are persuaded, can be more erroneous than this idea, and we believe that, so far from interfering, the Pan-American will actually help to increase the attendance at the Rome meeting. Many physicians from the Southern Republics, having already taken the long journey necessary to bring them to the Washington meeting and the World's Fair, will be prepared to extend their vacation and go to Rome. when, without this extra incentive, they might not have been persuaded to go to the International Congress.

The promoters of the Pan-American Congress were at pains to ascertain the date of the Rome meeting, so that there might be no interference, and with this object wrote to Dr. Baccelli several months ago. The latter replied that the Rome meeting would probably be held during the last week of September or the first week of October, although the exact time had not been definitely settled upon. This reply was not received until after the meeting of the Committee in St. Louis, when the date of the Pan-American had been already fixed for the first week in October; but when it was learned that this would interfere with the International, the time was changed to the first week in September. This will make it easy for those who desire to attend both meetings to do so, and is evidence that the Committee of the Pan American Congress desire to promote rather than to antagonize the International. The Washington meeting must, of course, be held in 1893, in order to afford the opportunity to the Latin-American members of visiting the World's Fair, and the fact that that is also the year for the assembling of the International Congress is but a coincidence, which will, however, be of distinct advantage to both bodies.

The organization of the Pan-American Congress is in the hands of good men, the National Committee is a thoroughly representative one, and the delegates thus far selected from the other countries of the Continent are men of eminence at home, and many of them of an international reputation as well. The idea of an American Congress has been well received in our sister Republics, and, now that the danger of a hostile meeting with one of them has been happily averted, there is every reason to anticipate a most successful meeting, and one that will be productive of mutual advantage and pleasure to all who take part in it. And we are confident that the entire profession in this country will labor as a unit to aid the Committee in their good and patriotic efforts, and to further in every possible way the success of the first Pan-American Medical Congress.

YELLOW FEVER AT SANTOS.

EVERY vessel arriving at this port from Santos brings tidings of the continuance of the yellow-fever pest in that unfortunate city. The disease has prevailed there with unusual severity for about two years, but since the beginning of the hot season last fall, it has raged with unparalleled malignancy. The city is the shipping port for a large section of Brazil, ranking next to Rio de Janeiro in the volume of its exports and imports, and it is among the foreign sailors that the epidemic finds the chief material for its victims, although large numbers of natives and acclimated foreigners have also died during the past few months.

The cause of this outbreak of disease is very apparent. For years, ever since the foundation of the city, in fact, up to a comparatively recent time, all the refuse of the city was thrown into the waters of the bay or river on which the town lies, and was there allowed to accumulate. About two years ago the building of stone docks in place of the old wooden wharves was begun, and this brought to the surface the old accumulation of filth. At the same time the yellow fever, which has always had its home in this unhealthful city, suddenly assumed an unwonted virulence. The city authorities have done little or nothing to stay its ravages, and, as fresh material has been continuously supplied in the persons of unacclimated sailors, the epidemic has naturally shown no signs of abatement.

There is a foreign hospital in the city attended by American and European physicians, through whose care many lives have been saved, but they can only help the sick and can do little in the way of prophylaxis beyond cautioning the captains of vessels against giving shore leave to their men. The city authorities of Santos are the ones upon whom rests the responsibility for this frightful loss of life, and in the face of their supineness there seems to be little hope of a subsidence of the epidemic. Perhaps, after the trade of the port has been destroyed, they will wake up to a realization of their criminal stupidity in suffering their city to become a plague spot and a disgrace.

GROWING FEVER.

CERTAIN French writers, notably M. Bouilly, have had much to say in recent years concerning a fever occurring during the period of growth, which they regarded as a morbid entity and dignified by a special name, "la fièvre de croissance." According to the author above mentioned, the disease is characterized by three special symptoms, to wit, fever, epiphyseal pain, and an increased rapidity of growth of the child. In addition to Bouilly, other writers, such as Bouchut, Gombault, Duchamps, and Dally, have lent the weight of their authority to this

view, so that, in France at least, the disease has been granted a definite place in nosology.

M. Barbillion, however, writing in the *Revue des Maladies de l'Enfance* for January, 1892, attacks this theory, and contends that there is no such disease, but that the fever observed is merely symptomatic of some recognized morbid condition. This may be acute rheumatism, mild typhoid fever, malaria, acute indigestion, ephemeral fever, or in some few cases osteomyelitis, or even simple fatigue, which is not infrequently accompanied by a rise of temperature in children. An increased rate of growth, he holds, is a very common accompaniment of pyrexial states in the young, and this in itself would be very apt to give rise to slight pain at the epiphyses of the long bones. Thus the two characteristic symptoms of epiphyseal pain and rapid growth may be the result simply of increased bodily temperature, and this latter can be due to any of the conditions mentioned. The author believes therefore that the so-called fever of growth has no existence as a disease *sui generis*, and that it is entitled to no place in the catalogue of independent morbid states.

ABOLITION OF ELECTRICAL EXECUTION.

Every enforcement of execution by electricity emphasizes the objection to the method. The promises made by scientific executioners that murderers shall be despatched speedily, painlessly, and pleasantly have fallen so far short of realization that the expected reactionary protest from the outraged public shows itself in the attempt to repeal the present cruel law.

Thus far every attempt at perfecting the abominable means to the horrifying end has been a failure, and it is high time to call a halt in the revolting experimentation enacted at every execution. All the victims have been killed, it is true; but how? In every case repeated strokes were necessary, with torturing intervals for discussion and disputation among the scientific experts—the grim tussel with death timed by stop-watches while the victim is writhing between scorching electrodes. The details of this dreadful business transcend in cool brutality anything that can be imagined, and yet we are assured that this is the new and approved way of doing the victim to death. How long must these sickening experiments continue before a repeal of the obnoxious law is possible? If we must have capital punishment let it be at least humane in its execution. A strong rope is always sure, is easily worked, and appeals to a higher civilization as well as to the ordinary necessities of the most primitive community.

ADVERTISING FOR DISPENSARY PATIENTS.

We are pained to notice a disposition on the part of some of our friends connected with public clinics to add another to the already long list of abuses of medical charity by advertising for free patients in the daily papers. It is difficult to see what the end may be if this practice becomes prevalent. We are speaking for the young practitioner when we protest against it. There should be no necessity which makes this method of securing material possible. It is an open bid against the bread and butter of the young man who must depend upon just such patients as the dispensary coaxes to its doors by such advertisements. If the clinics are so eager to go into the highways and byways for clinical material there will soon be no pay-patients among even the middle classes. It is not enough of an excuse for these so-called charities to declare that it is for the good of the sick poor. In reality it is apparent that the purely business element of these dispensaries is the uppermost consideration in the minds of their faculties, and it is no more to be considered from ethical points than is open advertising by the needy individual medical man. There are two sides to this question. The colleges and dispensaries cannot afford to make enemies of the rising generation of practitioners, for the reckoning will not be far distant. We advise these charitable institutions to withdraw their advertisements else they may hear more on this subject.

PROGNOSIS IN MANIA.

The Bulletin of the Belgian Society of Mental Medicine for December, 1891, refers to Willerding's interesting communications upon the subject of prognosis in mania. The author's study of 322 cases admitted to the Hildesheim Asylum, from January, 1878, to August, 1890, includes observations of all kinds of mania. Seventy per cent. of all cases recover within a few months. Early restraint has a most beneficial effect upon the course of the disease. Neuropathic heredity has no unfavorable influence upon prognosis. The outlook is good in mania following slight cranial trauma. The younger the patient, the greater the chance of recovery. In regard to the termination and duration of mania, prognosis is good in so far as it is due to organic, puerperal, or alcoholic cause. Return of menstruation, with coincident slight psychic improvement, is an almost certain sign of ultimate recovery. Among adverse symptoms that necessarily influence prognosis unfavorably are convulsions and paralytic phenomena, the gravity of the case itself, periods of sudden excitement in the course of puerperal mania, or mania following slight cranial traumatism, and abrupt cessation of mania. This sudden termination suggests the strong probability of speedy relapse, or a transition into periodic mania. A notable increase in weight before the mental abnormity has disappeared is an unfavorable sign. Prognosis in periodic mania is always discouraging. Definite and complete recovery is hardly to be expected. After a certain number of attacks of mania, of whatever kind, there is marked weakening of the intellect.

ABNORMITIES IN DEGENERATES.

Among epileptics, asymmetries are inherent even in minor details of the organism. Imprints of the ball of the fingers and great toe have been taken by Féré in one hundred and eighty-two cases of epilepsy. These imprints in general confirm Dalton's researches. The tendency to variation in the tactile substance increases from the little finger to the thumb, except in the ring-finger. Energy and rapidity of movements decrease from the thumb to the little finger. Asymmetry of imprint exists in nearly half the cases. This is an interesting fact, for asymmetry elsewhere is recognized as one of the most frequent and important characteristics of degenerates.

The nose, the most thoroughly original and distinctly

individual feature, said by the French to be the only one that cannot be "made" by art, presents in idiots deviation to the left almost amounting to deformity. The deviation exists in more than half the cases under observation. Revillet's records are worthy of note. Of common occurrence among idiots he finds hypertrophy of the mucous membrane of the septum and turbinated bone, an affection the observer considers relatively rare among persons of sound mind. Narrowing and obstruction of one nasal fossa, due to this marked deviation of the septum, are in themselves sufficient pathogenetic cause for this condition. Both nasal fossæ are usually affected with chronic catarrh.

Ocular phenomena in mental disease have received much attention of late. Excavations of the papilla, frequent in the eyes of normal persons, Royet affirms is the rule among the insane with suicidal impulses, and among those hereditarily disposed to insanity. Idiots and imbeciles, from the ocular point of view, may be divided into two classes. The first, the hypermetropics, are generally those whose mental infirmity dates from intrauterine life. The second class, on the contrary, emmetropics and myopics, are victims of dementia beginning in earliest childhood.

THE METHOD OF ZADIG.

Before the North London Medical and Chirurgical Society, Dr. T. Lauder Brunton recently delivered an address in which he advocated the method of Zadig in medicine; Zadig being a personage introduced to the world by Voltaire, and represented as retiring from Babylon on account of general disgust with life and chronic boredom. Upon the banks of the Euphrates, in a lonely place, Zadig studied plants and animals until he saw a thousand differences where others could see only uniformity. Zadig is also that interesting observer who accurately described to the Fakir, in the Syrian Desert, the lost camel which he had never seen, by carefully noting every form of circumstantial evidence in the region through which the animal had passed. This method of tracking, Dr. Brunton advocates in medicine, as a direct help to treatment. Without removing the cause, direct measures may prove fruitless. And he cites, as an illustration of this, the case of a young physician in a clinical service involving heavy work and great worry, whose nervous dyspepsia was promptly relieved by the timely administration of physic to his irritable and crusty superior, the chief of clinic.

The method of Zadig might explain why cases come in a run, bronchitis one day, rheumatism another, and exacerbation of nervous disease on a third. What connection is there between such phenomena and meteorological conditions? Converts to the method of Zadig might each week in one word jot down the kind of cases that appeared in greatest numbers, and individual notes might then be classified by one person in charge of them all, so as to give the general results.

Telegraphic communication of the approach of storms is now almost universal. In the near future, invalids as well as seamen may reasonably hope to prepare for what is coming and ameliorate the inevitable. By carefully watching the papers it will later be possible to avert catastrophe by extra flannel or bromide of potassium. But this day of mitigated evils can only become a substantial fact by elaborate study according to the method of Zadig.

PINEAPPLE JUICE.

Some time ago the late Dr. V. Marcano, of Venezuela, noted that pineapple juice contained a proteid digesting substance. No careful study of this fact was, however, made by him. Recently, Professor R. H. Chittender, assisted by Messrs. E. P. Joslin and F. S. Meara, have investigated the matter fully, and announce facts which are likely to give to the succulent pineapple a prominent place in dietetics.

Pineapple juice is an acid fluid of specific gravity of 1.043. An ordinary pineapple yields 600 to 800 cubic centimetres of it. The proteid-digesting power is quite remarkable in its intensity. Three ounces of the juice will dissolve ten or fifteen grains of dried albumin in four hours. The action takes place in acid, neutral, or even alkaline media, thus resembling trypsin more than pepsin. It acts best in neutral solutions. The pineapple juice contains also a milk-curdling ferment. Professor Chittenden does not seem to be aware that a well-known meat powder is prepared, or is said to be prepared, with the help of pineapple juice.

News of the Week.

Leprosy is said to be increasing at an alarming rate in Japan, and the native journals are urging the authorities to take measures for its repression.

Prize of the Société Médicale des Hôpitaux.—The Hospitals Medical Society of Paris offers a prize of 1,000 francs ($200) for the best essay upon "Artificial Feeding of Infants." The competitive papers must be sent to the Secretary of the Society not later than July 1, 1892.

Professor Quatrefages, of Paris, died in that city on January 13th, aged eighty-four. He was a member of the Académie de Médecine, and was well known for his writings on anthropology.

More Deaths from Chloroform in London.—During the second week in January two more men died in London hospitals as a tribute to British conservatism or obstinacy. A man, aged fifty, suffering from a fracture of the leg, died of chloroform poisoning at Guy's Hospital; and one, aged forty-five, with cancer of the tongue, was relieved of all further trouble in the same way at University College Hospital. It is getting to be very dangerous to fall into the hands of a London surgeon.

An Alleged Baeillus of Gout.—Dr. Edward Grün writes to *The Lancet* that he has, in three consecutive cases of acute gout, found the blood to be swarming with a long encapsuled bacillus, side by side with which numerous crystals of biurate of soda were to be seen. He promises to give a full description of the bacillus in a future communication.

The Origin of the Name "Grippe."—In a meteorological journal kept in Versailles, in 1743, it is stated that during the months of February and March there were

many cases of nasal and bronchial catarrh, and that "the king (Louis XV.) named this disease *la grippe*." In the same journal it is remarked that bleeding was not useful, but that those who had not been bled and who drank a great deal recovered much the most rapidly from the attack.

A Snuff for the Grip.—The powder of the root of *Ligusticum Levisticum* (lovage) has been highly recommended by several medical gentlemen as an antidote for the catarrhal and other symptoms of grip. It is used as an impalpable powder of the root and snuffed as an ordinary sternutatory, allaying the distressing symptoms in a short while and placing the patient in a comfortable condition. The German variety of lovage is said to possess the qualities named.

Another Case of Quintuplets.—Dr. J. M. Tracy writes: "Referring to your query as to the occurrence of quintuplets, I would say that in 1872, in Dubuque, Ia., a Mrs. Woodward was delivered of five well-formed infants weighing $1\frac{1}{4}$, $1\frac{1}{4}$, $1\frac{3}{4}$, 3, and $4\frac{1}{2}$ pounds, respectively. Two gasped a few times only, one lived thirty minutes, one six hours, and one several days."

The Jacksonville Insane Asylum.—The telegraphic report of a scandal in this institution, referred to in an item in a recent issue, seems to have been incorrect. Dr. J. D. Fernandez, of that city, writes: "We have no insane asylum in Jacksonville, and never have had one, all the insane of the State being sent to the asylum at Apalachicola, where they are well and humanely cared for." We are glad to learn that the report was incorrect.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1892. Essays intended for competition may be upon any subject in Medicine, and must be received by the Secretary of the College on or before May 1, 1892. It is a condition of competition that the successful essay, or a copy of it, shall remain in possession of the College. CHARLES W. DULLES, *Secretary*.

A New Swedish University has recently been established at Gothenborg. It is to be entirely independent of State aid and control, an endowment fund of over half a million dollars having been subscribed by private persons.

Yellow Fever.—The usually well informed *Lancet* asserts in a recent issue that yellow fever is always found more or less in the southern part of the United States, and that "certain cities like New Orleans, Rio Janeiro, and Santos are frequently scourged with this disease." We wonder if the writer knows where the three cities mentioned are situated?

Mortality Caused by Wild Animals in India.—The mortality caused by wild animals in 1890 was considerably less than in the previous year, being a total of 2,460 against 2,724. Tigers and leopards accounted for the loss of 798 lives, and wolves 87. Returns more or less doubtful state that 64,500 cattle were destroyed by wild animals. A marked decrease has taken place in the number of wild animals destroyed, as the total for the year was only 14,604 against 17,638 in 1889. The total number of persons killed by snakes was 21,412, as compared with 22,480 in 1889. The number of snakes destroyed is returned as 510,659, of which four-fifths are said to have been killed in the Bombay Presidency. *Indian Medical Gazette.*

Drinking in the German Army.—German military papers publish alarming statistics as to the spread of drunkenness in the German army. In Saxony the consumption of spirits has somewhat diminished, but the diminution is more than made up by the drinking of beer.

Tuberculosis in Buda-Pesth.—Professor Fodor, of Buda-Pesth, asserts that that city occupies a bad preeminence among the large centres of population in Europe in point of its mortality from tuberculosis. The yearly average of deaths from that disease in the Hungarian capital is from 590 to 600 per 100,000 inhabitants. Professor Fodor attributes this state of things to the defective paving of the streets, owing to which the atmosphere is charged with an abnormal amount of dust. Taking this in conjunction with the recent closing of all the schools in the city owing to the prevalence of scarlet fever and diphtheria in the city, it seems as though the forthcoming meeting of the Congress of Hygiene at Buda-Pesth will be of the nature of a council of war held on the battle-field. With so much material for the most instructive object-lessons around them, the deliberations of the eminent sanitarians who take part in the proceedings should be of a highly practical character.—*British Medical Journal.*

An Italian Orthopedic Society.—The Italian Orthopedic Society was organized at a meeting of the chief representatives of the specialty in Italy held at Milan on December 20, 1891. The first annual meeting will be held in that city in April, under the presidency of Dr. Gamba, of Turin. Dr. Bernacchi, of Milan, is the provisional secretary of the new society

Epidemics Following the Earthquake in Japan.—The *Sei-I-Kwai Medical Journal* reports that typhoid fever has broken out in the prefectures of Aichi and Gifu, where there was so much destruction by the recent earthquake. It is also reported that simple conjunctivitis is prevailing in those places, and it is believed that the disease is due to the atmosphere being filled with ashes and dust after the earthquake and fire.

The Montreal General Hospital is to receive $60,000 through the will of the late Mrs. Phillips of that city.

Editorial Changes.—Drs. Nicolson and Stockton have retired from the editorial staff of the *Southern Medical Record*, their places being filled by Drs. Gaston and Westmoreland.

Consanguineous Marriages in Prussia.—According to a recently issued volume of the *Preussische Statistik* there were 240,996 marriages in that country in 1889, of which number 1,375 were between first cousins, 110 between uncle and niece, and 28 between nephew and aunt. Thus of every thousand marriages there were between cousins-german, 5.71, between uncle and niece, 0.46, and between nephew and aunt, 0.12

A Large Lipoma.—Dr. E. Hahn recently reported to the Berlin Medical Society the removal from a man, aged sixty-four, of a lipoma weighing over twenty-four pounds. It originated from the shoulder and extended along the posterior surface of the arm to the elbow, the free portion hanging down as far as the hand.

Suicide Among Physicians.—The *Boston Medical and Surgical Journal* notes the fact that physicians not only headed the list of suicides last year, but that they have headed it every year in the last ten. This promises to be still more conspicuous this year, as in the first twelve days of January no less than seven physicians committed suicide in the United States.

The Pan-American Medical Congress in the United States of Colombia.—A permanent organization of the coming Congress has been effected in the United States of Colombia by the election of secretaries of sections, and of the auxiliary committees, composed of delegates from the principal cities of the republics. The following medical societies have been selected as auxiliaries of the Congress: Academia Nacional de Medicina, Academia de Medicina de Medellin, and Sociedad de Medicina de Cauca.

The University of Dorpat, in the Baltic provinces of Russia, which has hitherto had German professors, and has been attended by German-speaking students, is to be Russianized, the government having given notice that after a certain date, in the near future, only the Russian language will be allowed in the lectures and examinations.

Suicides in Russia average 2,215 a year.

An International Congress of Obstetrics and Gynecology will be held in Brussels, September 14 to 19, 1892.

Trichinosis.—There is an epidemic of trichinosis in Russian Poland, and many deaths have occurred. In one village an entire family, containing eleven members was exterminated by the disease.

An Influenza Number.—The issue of the *Times and Register* is devoted to articles on influenza. But, alas! after reading it one weeps to find that the disease is still the same old, mysterious grip, and the means for its prevention, not to say cure, is yet to be found.

Dr. José Maria Romero, first president of the National Academy of Medicine of Peru, and dean of the Faculty of Sciences in the University of Lima, died last autumn in Lima.

A Congress of Socialist Students was held recently, and resulted in the adoption of a prodigious number of resolutions. Among other things they demanded the repeal of all laws against international labor organizations, the enforcement of one day of rest in the week, the forbidding of work underground for women and children, and they also insisted upon the adoption of various measures bearing upon the moral and material amelioration of woman's lot.

M. Moutard-Martin died in Paris the day before Christmas. He was president of the Académie de Médecine in 1890.

Another Editorial Change in Philadelphia.—It is somewhat puzzling to follow the changes in the editorial management of some of our esteemed contemporaries in Philadelphia. The *Therapeutic Gazette* has again changed editors, being now entrusted to the care of Drs. Hare, de Schweinitz, and Martin. Dr. Hare brings a ripe editorial experience, gained on several of the journals in Philadelphia, to aid him in his new undertaking.

Precautions against Yellow Fever in the Harbor of Rio de Janeiro.—In a letter addressed to the consuls-general in Rio de Janeiro, Dr. José de Souzada Lieviera, the inspector-general of the health of the port, says that all vessels upon their arrival in the harbor are visited by his aids, who instruct the captains in the hygienic measures which it is necessary to follow, such as the daily washing of their ships with carbolic acid and water, and the disinfection of the water-closets with chlorate of lime and chloride of zinc. The consuls are asked to use their authority to see that these rules are carried out, and to prohibit the sailors from coming ashore, as, owing to their excesses, they fall easy prey to yellow fever. They are also requested to instruct the captains to cease labor during the heated hours of the day, and to hoist the signal for medical visit as soon as the first symptoms of any disease are seen.

Mortality in the French Army.—In 1891 the mortality from all causes in the French Army was 5.5 per 1,000, by far the largest number of deaths being from tuberculosis and typhoid fever. In 1886 the mortality was 6.41 per 1,000.

A Medical Strike.—There is a vacancy on the medical staff of the hospital in Tilsit, Prussia. When the vacancy occurred the municipal authorities advertised for candidates, stating that the salary would be 1,000 marks ($250) a year. Thereupon the local medical society caused an announcement to be inserted in the paper, immediately below the advertisement of the city fathers, stating that the salary was too small and that none of the physicians of the place would accept an appointment for less than 1,500 marks. They also advised physicians from outside to think awhile before presenting themselves as candidates for the position, intimating that the lot of anyone accepting the appointment would not be a happy one. The mayor of the town acknowledges that the salary offered is very small and almost insulting in its minuteness, yet he thinks the city can buy some needy doctor for the price.

The Belgian Law against Hypnotizing.—Belgium is the first country to make hypnotizing an offence against the law of the land. The law recently approved by the Parliament in Brussels is as follows: "1. Whoever exhibits an individual hypnotized by him or by another shall be punished by imprisonment for from two weeks to six months, and by a fine of $5 to $200. 2. Any person, not a physician, having hypnotized an individual under twenty-one years, or one not in full possession of his mental powers, shall be punished by a fine of $5 to $200, even when the hypnotized individual has not been exhibited publicly. 3. With imprisonment shall be punished, moreover, every person who, with the intention of cheating or otherwise injuring, causes a hypnotized individual to sign a paper containing a contract, disposition, obligation, release, or declaration of intention. The same punishment shall be inflicted also upon the person deriving benefit from such a paper."

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 6, 1891.

GEORGE L. PEABODY, M.D., PRESIDENT, IN THE CHAIR.

Case of Thrombosis of Cerebral Sinuses.—DR. ANDREW H. SMITH related the case. Patient, male, aged thirty-two, unmarried; no specific history. Had not been feeling quite well for two or three days, but attended regularly to business. On the evening of October 10th he took a quinine pill on going to bed. At about 1 A.M. his brother, who occupied the room with him, was awakened by his loud breathing. He found him struggling violently, apparently in a convulsion, speechless, and seemingly unconscious. I saw him about an hour later. His whole body was then in a state of tetanic rigidity; the elbows and wrists flexed, and the thumbs extended and abducted. The head and eyes were turned to the left. Pupils symmetrical and responsive to light. The whole body was wet with perspiration, and the sheet, in which he had wound himself up tightly, was saturated. I have never seen such profuse perspiration even in a Turkish bath. The respiration was stridulous rather than stertorous, and accompanied by loud tracheal râles. There was at this time no puffing of the cheeks or lips.

The picture resembled so closely that of poisoning by strychnine, that my conclusion was that the quinine pill which he took on going to bed had contained by accident a portion of strychnia, and I sent out for chloroform and atropin as antidotes.

But before the messenger returned the spasm in the right arm began to relax, and attempts at voluntary motion were observed. A few moments later the patient took a handkerchief which was offered to him and wiped his face. A relative to whom he was much attached coming in at that time, there was evident recognition followed by loud weeping. Being told to put out his tongue, he was able to do so with difficulty, the point deviated to the left. The left side of the face was now seen to be relaxed, and the left cheek puffed somewhat in respiration. The whole left side remained rigid, and the slightest tap on the tendon of the patella would cause an excessive jerk. Right leg flaccid, patellar reflex absent. Swallowing difficult. Pulse at this time, 98; ax. temperature, 101° F. Supra-pubic region depressed and resonant on percussion.

The motion of the right arm soon became less, and gradually was replaced by paralysis. The mind seemed to be active for some time, and the eyes expressed realization of what had occurred. But little by little this was replaced by apathy, and at last by coma. Death took place forty-four hours after the attack. During the last twenty-four hours the temperature stood at 102° to 103° F.

Apparently no urine was excreted from the moment of the attack. Frequent examination always showed the supra-pubic region depressed and resonant. Soon a urinous odor began to pervade the whole body, and before death this was so marked that it was communicated to the hand when laid upon any portion of the surface. The relation of this anuria to the excessive perspiration is a question of interest. It seems scarcely probable that the inactivity of the kidneys was due to the extreme activity of the skin, as this would not account for the odor imparted to the perspiration. Nor can the reverse of this relation be accepted as probable, since the perspiration began with the seizure. Besides, suppression of urine is not ordinarily accompanied by marked increase of perspiration. It seems probable, therefore, that both conditions depended upon a common cause, and this may have been a vaso-motor paresis of central origin, and due directly to the intra-cranial lesion.

Autopsy. *Dura Mater.*—Greater part of lateral sinus had a rather firm, friable clot in it, slightly adherent in part to the walls. In the right lateral sinus a large dark, friable clot, not adherent, with some brownish tints. In left lateral sinus, the same condition existed, but it was less abundant and less marked; same also in right petrosal sinus, but less firm and characteristic. In the left petrosal and straight sinuses similar material existed.

Pia Mater.—The vein which lies half an inch behind the fissure of Rolando on the left side was distended and felt hard, as if filled with an ante-mortem clot, and the median end of the corresponding vein on the right side is in a similar state for about half an inch. The vein which runs obliquely across the middle of the convexity of the right temporal lobe is also hard.

Principal vessel in base of same lobe is firm, white, and completely occluded. The basilar arteries appear normal. Just at the origin of the left middle cerebral there is marked atheroma. Vertebral artery, just at its origin, has extremely thick walls, and the remaining lumen closed by what seems to be an ante-mortem clot. Venæ Galeni filled with a firm clot, principal vessel covering the pia mater in left cerebellum also filled with clot.

Right side of pons showed marked softening, with some yellowish and pink discoloration, also loss of structural markings. No other abnormal conditions.

DR. HERMAN BIGGS had seen two cases of thrombosis of the cerebral sinuses recently. The first was in the case of a young girl who had lately become an inmate of a house of prostitution of rather the better character. For some reason the house was raided by the police and she was taken to a station-house. She felt her disgrace very keenly, at first was violent, was apparently in an hysterical attack which gradually became less marked; but she remained quite nervous for about twenty-four hours, then grew morose and melancholic, and died at the end of about five days. The autopsy revealed absolutely nothing except complete thrombosis of the straight sinus, extending somewhat into the venæ Galeni.

The history of the second case was very similar. A woman was admitted to Bellevue apparently in a violent hysterical paroxysm. The symptoms became somewhat less marked. There was no rise of temperature. She gradually became very stupid and died, and at the autopsy they found thrombosis throughout the whole of the superior longitudinal sinus, extending into several veins of the convexity, and nothing else.

DR. R. F. WEIR remarked that it was probably superfluous to ask Dr. Smith and Dr. Biggs whether in their cases there was any aural affection. Surgeons, he remarked, were in the habit of looking through their own spectacles at these cases. They saw a great many cases of thrombosis of the lateral sinuses due to ear trouble, and were now also led to believe that the straight sinus was capable of being involved from aural disease. Cerebral thrombosis might also take place from naso-pharyngeal disease.

Dr. Smith and Dr. Biggs said there was no aural trouble in their cases.

DR. BIGGS said he had that day made an autopsy in a case in which there was found thrombosis of the superior longitudinal sinus, extending into the left and right lateral sinuses, and into the right superior and inferior petrosal sinuses, following fracture of the skull in the occipital region and most profuse serous discharge from the ear. The discharge continued about forty-eight hours, and it was estimated that not less than three ounces of serum was discharged from the right ear in twenty-four hours.

DR. A. B. BALL inquired of Dr. Smith whether his patient had been anæmic, and Dr. Smith replied, not particularly; he was a man of a good deal of energy and activity, and had complained simply of not feeling very well, but not of being sick.

Dr. Ball thought we should recognize two classes of cases of thrombosis of the cerebral sinuses. In the one class, the trouble started outside the cranial cavity, like in cases of aural disease referred to by Dr. Weir, or of in-

juries to the bones. The other class arose, as it were, spontaneously from trouble inside the skull, and their explanation was not very clear. The cases related to-night, he thought, were difficult to account for. The only case which he ever saw he reported about three years ago. It occurred in a servant girl who was in fair health, but had more or less marked chlorosis. She was taken suddenly with severe pain in the head, was obliged to go to bed, was brought to the hospital in a stupid condition, lived about three weeks, and at the autopsy marked thrombosis was found in most of the cerebral sinuses. He was able in a short time to collect records of twelve similar cases of thrombosis occurring in anæmic persons, and it would seem the accident was not infrequent in this class of patients.

We were apt to attach too much importance to the mere occlusion of the sinuses, whereas we had strong evidence that obstruction of one, or even of two or three, of the sinuses of the brain did no serious harm. Most of the sinuses emptied into the torcular Herophili; even those at the base were indirectly connected with it. In other words, there was free communication between the several sinuses, and occlusion of one or two did not seriously disturb the circulation. It had been shown by experimentation that, in dogs, nearly all the cerebral sinuses could be occluded without producing unpleasant effects. The experiments were carried out by occluding one after another of the sinuses with wax. It was found that on either side of the wax no thrombus had formed, proving that mere slowing of the blood-current was not the cause of thrombosis.

The diagnosis was difficult, yet if he should meet with a case presenting symptoms which his had presented, and which he had the opportunity to study for three weeks, he would strongly suspect thrombosis of the cerebral sinuses. The symptoms were different from those seen in any other cerebral affection, the difference consisting largely in their changing character. For instance, a limb which was paralyzed one day would be normal the next day, a pupil contracted one day would be dilated the next. Such changes would not be observed perhaps in the cases progressing more rapidly to a fatal issue. In his own case he did not even think of thrombosis of the cerebral sinuses, and he believed that was true of the history of most cases.

Dr. Kinnicutt said that the cases which he had seen presented the changeability in the symptoms mentioned by Dr. Ball—paralysis of a limb for one day only, and so on.

The President remarked that cases of thrombosis of the cerebral sinuses arising from ear disease, erysipelas, etc., were clearly due to sepsis, but where the thrombosis occurred in marasmus, rheumatism, etc., it was hardly probable that sepsis would account for it.

Stated Meeting, December 4, 1891.

George L. Peabody, M.D., President, in the Chair.

Fatal Jaundice without Obstruction of the Ducts.—Dr. Francis Delafield presented a verbal communication on this subject. He said: It is well known at the present time that the ordinary view held regarding the causation of severe and fatal jaundice is, that it must be necessarily due to some obstruction which prevents the bile formed by the liver from passing into the intestine. It seems to be the ordinary opinion that in all such cases the liver continues to produce bile, but that the bile, not being able to escape into the intestines, is re-absorbed, and then produces certain symptoms. There is still some difference of opinion as to the interpretation of these symptoms, but I think that every one will be agreed as to the ordinary clinical picture. If a person has cancer of the common bile duct, or calculus in this duct, or if he has chronic catarrhal inflammation or narrowing of it, the symptoms will be practically the same, quite independent of the cause of the obstructive jaundice. Such patients have a jaundice which increases steadily until death. They have very marked loss of nutrition, they lose flesh and strength rapidly, and in an appreciable degree. They have decided disturbance of the stomach and bowels; they have difficulty in taking food; they vomit more or less; they may have either constipation or diarrhœa; they have more or less itching of the skin, which belongs to icterus; they have a decided disposition to bleed from different parts of the body, from both the mucous membrane and the skin. Passing to the later stages of the disease, there regularly develop cerebral symptoms, as delirium alternating with stupor, and so they go on until they die. We have been told that such patients do not die from the accumulation of the bile in the blood and in the tissues, but from the interference with the functions of the liver. At all events, whatever the cause, such real obstructive jaundice always gives the same symptoms.

Now, besides these ordinary cases of obstructive jaundice, I think it is by no means uncommon to find patients behave in just the same way as if they had an obstructive jaundice, and yet in whom at death no obstruction is found. It seems to me that the frequency of such cases prevents our overlooking them. And until they can be explained we have something before us which cannot be made to agree with the prevailing theories of fatal jaundice. The patients who behave in this way and die from jaundice in exactly the same way as other patients who have obstructions of the common bile-duct, have, for the most part, hypertrophic cirrhosis. A smaller number have fatty liver, but most of them simply have hypertrophic cirrhosis.

As regards the character of the hypertrophic cirrhosis, the liver, though always large, may be either smooth or nodular.

The new-growth of connective tissue which belongs to the cirrhosis may be diffuse; it may surround small groups of the acini; it may surround large groups. The liver-cells may be normal; they may be granular; they may be fatty. In the new connective tissue we find the appearance of a new-growth of the bile-ducts, which at one time was supposed to be characteristic of hypertrophic cirrhosis, but which is readily seen in all the forms of cirrhosis, whether hypertrophic or not. The large bile-ducts are normal; they are empty, not dilated. The gall-bladder is of natural size; very often empty.

Now, this appearance of the large bile ducts and the gall-bladder is exactly opposite to that which we find in obstructive jaundice. If a person have a calculus in the common bile-duct; if he have a catarrhal inflammation of this duct, or a new-growth affecting the same part, and die of obstructive jaundice, we find the large bile-ducts dilated and containing bile; we find the gall-bladder, unless the cystic duct has been obliterated by previous disease, distended and containing bile. We find what we expect to find with an obstruction, that is, dilatation of the gall-ducts above; but in the other class of cases, the cases without any obstruction, it is always noticeable that not only is there no obstruction, but there is absolutely no dilatation of the bile-ducts or of the gall-bladder, and there is no accumulation of bile in the bile-ducts or gall-ducts, yet the liver itself will be regularly bile-stained. Still further, in going through all the large bile-ducts in these cases, nothing will be found out of the way. No thickening, no mucus, no evidence of any trouble whatever.

In the stomach there are the changes which one expects to find with any cirrhotic liver. There seems to be hardly any old cirrhosis of the liver without more or less catarrhal inflammation of the stomach. In the duodenum also there will be the evidences of catarrhal inflammation, and this might seem to be a reason for the jaundice. It might be supposed that these cases were like the ordinary cases of acute duodenitis which do produce obstructive jaundice, but yet the conditions are different. If an acute duodenitis produce a jaundice, you will find more or less accumulation of bile in the bile-

ducts and in the gall bladder. But in these cases, although there is an acute duodenitis, there is absolutely no dilatation, and no accumulation of bile in the ducts, or in the gall-bladder. Or if there is a slight amount of bile in the gall bladder, it can be pressed through the duct into the duodenum without the slightest trouble.

The kidneys in these patients present for the most part, unless they have previous chronic nephritis, the chronic degeneration which may accompany any obstructive jaundice.

The symptoms of these patients are those of an ordinary obstructive jaundice. I do not think, so far as the symptoms are concerned, that you could distinguish them from patients with a new-growth in the bile duct, with a calculus in the bile-duct, or with a chronic inflammation of the bile-duct. They have a jaundice which increases steadily up to the time of their death, so that by the time they die the skin and all the tissues are discolored to an extreme degree. The urine, of course, contains bile-pigment, the fæces are white. In some patients, before the attack of fatal jaundice comes on there may be a history of attacks of slight jaundice which have come and gone. In some patients there will be a history of one or more ordinary attacks of gastro-duodenal jaundice, ordinary attacks of that kind with which we are all familiar, which run their course and pass over; but later the patient will have an attack of fatal jaundice.

With the increasing jaundice, which finally terminates fatally, they will have the ordinary inability to eat, the constipation and diarrhœa, the delirium and stupor; in some of them there will be a dropsy belonging to the cirrhosis, while in others this will be absent. In all the cases which I have seen, the disposition to bleed has been fairly well marked. In all of them the loss of nutrition has been very well marked. They all lose strength very rapidly, and in that condition they have died.

As regards the duration of the attacks, in the cases that I have seen, both during life and after death, they have lasted between three weeks and four months. What I have said positively belongs altogether to cases which I have followed to the post-mortem table.

Besides these positive cases, there was of course a larger number which were seen during life, and not after death. And it is the bearing of the certain cases upon the uncertain ones which seems to me a matter of interest. We all know that with cirrhosis of the liver, especially hypertrophic cirrhosis, jaundice is a symptom, and that it manifests itself in different ways; that some of the patients have attacks of jaundice which behave like ordinary attacks of acute gastro-duodenal jaundice, which last through days or weeks and disappear, and that is the end of the matter. I presume that those are examples of ordinary obstructive jaundice due to gastro-duodenitis. Then, besides these there are other patients who, although they have a little jaundice off and on, do not have a great deal; they do not seem to be poisoned by it. With this more or less jaundice they have no evidence of gastro-duodenitis, and I do not think that we have ever known what was the real cause of the jaundice in this class of patients. Then there are other patients (and these cases are perhaps of more practical importance) who for a long while have a good deal of jaundice. For example, I have under observation at present a lady, who for the last three years has been a good deal jaundiced all the time, sometimes more, sometimes less. She is always a good deal jaundiced, and yet at the end of three years she is able to be up and out of doors and look after her affairs. These cases of decided jaundice are, I think, of practical interest, because of the importance of knowing what is best to do for them.

When you see patients who are very decidedly jaundiced, and have been so for a considerable time, you naturally think that they have either a calculus in the common bile duct, or that they have a new-growth, or a chronic inflammation of this duct. If it is an old case you exclude a new-growth, because you know that that would destroy life within a moderate length of time. Thus you are brought down to the possibility of a chronic inflammation of the common bile-duct, or of calculus of the common bile duct. If the jaundice comes and goes, and if the attacks become worse and there is a rise of temperature, there certainly will be a good deal of reason for believing that the trouble is a movable calculus in the common bile-duct. Attention was called to that condition by Dr. Osler some time ago, and I suppose we all know that that is apt to be the case. For that reason I think it is of practical importance to recognize the fact that you may have a jaundice which exactly resembles an obstructive jaundice, and which can destroy life in just the same way, and yet after death you will not only find no obstruction, but absolutely nothing about the bile-duct or gall-bladder to make you think that obstruction was possible.

Dr. Kinnicutt said that the type of disease described by Dr. Delafield was of great practical interest.

A single criticism might be permitted, however. It was that the jaundice *per se* was not necessarily the cause of the grave symptoms and death in these cases. It was well recognized that very similar symptoms not infrequently occurred in various forms of hepatic disease, with or without jaundice. In certain cases of hepatic cirrhosis, similar profound disturbances of the nervous system were developed with little or no jaundice. Dr. Kinnicutt personally had been inclined to ascribe the train of symptoms detailed by Dr. Delafield, rather to a grave perversion or arrest of the functions of the liver, through which an accumulation of poisonous matters in the general circulation occurred, than to the mere presence of the constituents of the bile through absorption in the blood. This was in accordance with the theory of Murchison, Frerichs, and others.

Dr. Andrew H. Smith mentioned the fact that cases of jaundice had been reported due to strong emotion or other disturbance of the nervous system, and he thought it possible an analogous form of jaundice might arise from disease of the nerve supply of the liver. He had at present a case of jaundice in the Presbyterian Hospital which had existed for five months. The patient was nearly black, yet the obstruction was not absolute, since the stools were yellow and not clay-colored; there was the usual staining of the urine with bilirubin; the patient was very much emaciated. In this case there was no apparent change in the dimensions of the liver, no tumor could be felt. It was a singular fact that, while the skin was so deeply stained, the conjunctivæ were white.

Dr. Smith also mentioned the case of another patient, who had been sent to the hospital with the history of having had a similar deep staining of the skin for over six months. He died suddenly, and while there had been no history whatever of syphilis, yet they found gummatous tumors disseminated throughout the liver which were the only apparent cause for the jaundice, and it was assumed that they must, in spite of the negative history, have been of syphilitic origin.

Dr. Delafield said the theory which had been repeated by Dr. Kinnicutt had always seemed to him eminently unsatisfactory. This became apparent in comparing cases of obstructive jaundice due, say, to new-growth of the bile-duct, and the way in which they died, with the rare cases of cirrhosis in which the functions of the liver were apparently abolished. There were cases of cirrhosis of the liver, though rare, which had no dropsy, and they died from the cirrhosis or loss of function of the liver, without any lesion of any other part of the body. They showed the same loss of nutrition, they had toward the end the same cerebral symptoms as the cases with obstruction, yet he could not understand how one, on looking at both types, could say that they had essentially anything to do with each other.

While he hardly felt himself ready to break loose from the accepted theory that, to have a fatal jaundice, there must ordinarily be obstruction and the bile become re-

absorbed, yet he could not shut his eyes to the fact that there were fatal cases in which there was no obstruction apparent.

Dr. Kinnicutt said that the varying degrees of jaundice which occurred in the grave forms of anæmia had been explained by the destruction of the red blood corpuscles, which occurred in a marked degree in these cases. The hæmoglobin thus liberated evidently underwent certain chemical changes, and was converted into a pigment which gave all the reactions of bilirubin. Might not a similar process be accepted as an explanation of certain cases of jaundice without obstruction?

Remarks on Subdiaphragmatic and Rectal Abscess of Appendical Origin.—Dr. R. F. Weir then read a paper with this title. (See p. 173.)

Dr. George F. Shrady remarked that he had had no experience exactly similar to that related by Dr. Weir, but called to mind two cases of abscess of the vermiform process, one which burrowed its way up into the region of the liver, for which he made lumbar drainage, and another which he drained from the front. Both patients recovered. He had one case of abscess opening spontaneously into the rectum, which, after tedious treatment, finally recovered.

In another case, which had been neglected for a long time, the patient living in the country and being without medical assistance for a long period, the abscess seemingly had taken its rise at the vermiform process, burrowed up into the lumbar region a considerable distance, then downward, and it appeared to him, when he saw the patient, that it had found its way under Poupart's ligament and beneath the fascia of the thigh. He made free drainage in the groin and also in the posterior portion of the thigh, but the patient did not survive the operation long and died from exhaustion. At the autopsy a pus communication was found through the obturator foramen, which was rather unusual; the abscess also communicated with the bladder, and the patient had discharged pus with his urine for some weeks before he died.

Dr. W. T. Bull had seen but one instance in which a suppurative inflammation in the neighborhood of the appendix vermiformis had led to a subdiaphragmatic abscess, and but one in which it had led to an abscess in the neighborhood of the rectum; but these two conditions were present in the same case. He said he did not think we should make our inability always to determine the exact limit of the pathological process involved in catarrhal appendicitis an excuse to operate in every such case. He asked Dr. Weir whether he had not recommended such extreme interference.

Dr. Weir replied that he did not know that he had mentioned it.

Dr. J. D. Bryant said his own experience with cases of the kind reported by Dr. Weir had been limited to two. In both the abscess extended up to the liver, and occurred in hospital practice; in one, the symptoms were referable almost entirely to the supposed seat of the disease between the crest of the ilium and lower ribs on the right side; an incision was made in the flank, and a large cavity was found extending upward, as before remarked.

The other case he saw in consultation, and from experience with the previous one he ventured to predict that a large abscess existed behind the colon. He was unwilling to say whether it did, or did not, extend up to the liver. It appeared to be, in all probability, secondary to inflammation located over the colon, presumably intraperitoneal, which had subsequently extended to the situation which it occupied at that time. An operation was performed, and afterward the autopsy revealed facts entirely confirmatory of his diagnosis.

The reason for the extension of the abscess in this direction, or that, depended upon the anatomical situation of the vermiform appendix. At the last meeting of the Medical Society of the County of New York, he had given an analysis of one hundred autopsies with regard to the relations of the vermiform appendix to the colon, sigmoid flexure, etc. In one of the hundred cases the appendix was found behind the colon, extra-peritoneal, extending up to the liver. In another case it was behind the colon, but extended up toward the right flank, not going nearly so far as in the previous one. It was fair to assume that had the appendix in these cases been attacked by disease the abscess might readily have extended to the liver. In quite a number of cases, however, the appendix was situated directly behind the cæcum, and in them it would seem that, had perforation occurred, the inflammation might easily have followed the course described by Dr. Weir.

The speaker said he had had no experience bearing on the question of abscess extending into the pelvic cavity as a result of disease of the appendix. He had operated in one case in which he found the vermiform extending just through the brim of the pelvis, but not farther. He might add that in a number of the hundred autopsies referred to the appendix extended into the pelvis, and even down to the rectum.

The President said that some years ago a patient came under his care, the last weeks of his life, who was remarkably emaciated, had high fever, distended abdomen, very great tenderness over the abdomen, and apparently there was fluid in the cavity. He gave a history of nearly a year of pain in the abdomen, fever, frequent chills, and some sweating, and latterly distention of the abdomen. He supposed he had to deal with a case of tubercular peritonitis. At the autopsy, which occurred a few days after the patient came under his observation, he found an old abscess in the neighborhood of the appendix, which had passed up to the right of and behind the colon, entered the liver, and formed in it an abscess-cavity capable of holding a quart of pus. This hepatic abscess had ruptured through the lower border of the liver into the general peritoneal cavity, and produced purulent peritonitis, from which the patient was suffering when he came under his observation, and from which he died.

It might also be of interest to the Society to know that he had made an autopsy on the body of a former member of the Society, who had once given an account of an attack, evidently of abscess of the vermiform appendix, which had occurred to him during school life, years before any operation for this disease had been practised. Dr. Peabody found at the autopsy no vermiform appendix at all; it had been totally obliterated and its place taken by a fibrous band. This seemed fair evidence that the appendix had disappeared with the pus at the time of the attack, many years before.

Dr. Bryant recalled the case of a person in the city who had been treated for abscess of the liver; the abscess had been opened and recovery followed. Death occurred some time afterward from an entirely different cause, and it was found that the original cause of the first trouble had been an appendicitis.

Dr. W. M. Polk said that he had once related a case before the Medical and Surgical Society in which he made an opening for appendicitis in the situation described by Dr. Weir. The case was then six days old, and on the eighth day the pleura became involved, which rapidly produced a very large collection of fluid. At the end of a week evidence of active inflammation had subsided, and the patient recovered. He thought the suggestion with reference to operating through the rectum was a very important one. He recalled the case of a boy who had an attachment of the appendix down in the pelvis, and had he opened through the rectum, he believed the patient would have recovered. Having opened in the usual locality, the patient died, and at the autopsy the greater part of the inflammation was found confined to the pelvis. He had repeatedly seen the appendix located in the pelvis, in some instances extending even across the pelvis to the left side, the cæcum, of course, being on the right side.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-sixth Annual Meeting, held at Albany, February 2, 3, and 4, 1892.

(Continued from p. 160.)

THIRD DAY, THURSDAY, FEBRUARY 4TH.

Annual Reports.—DR. PORTER, Treasurer, read his report, which showed a balance in the treasury. The report of the Committee on Prize Essays was read by the Secretary. Only one competing essay had been received, which, while deserving, was not considered as coming quite up to the standard for the prize. Dr. Currier's proposed amendment to the by-laws, affecting the initiation fee of permanent members, was rejected.

Auxiliary Committee on Legislation.—The following was passed: *Resolved*, That the Medical Society of the County of Albany be requested to appoint an auxiliary committee on legislation of five members, to co operate with the Committee on Legislation of the State Medical Society when especially requested to do so.

DR. DANIEL LEWIS explained that the object of the resolution was to have some person present at the Capitol to represent the Society in opposition to bad bills, when it should happen that the members of the Committee on Legislation appointed by the State Society could not be present.

Report of State Board of Medical Examiners.—DR. W. W. POTTER read the report of the members of the Board who had been appointed on recommendation of the Society. The Board desired that the law creating the board of examiners remain at present unchanged. The report was accepted and a motion was passed, requesting that a published record be made by the board of those passing their examinations, so that county societies, and others interested, might know who were legally entitled to practise.

DR. FLOOD read the report of the committee appointed to consider the points raised in the President's inaugural address. The points were in general endorsed. They involved no important action. The recommendation regarding the Pan American Medical Congress led to a resolution appointing a special committee of five, the President to be ex-officio chairman, to take into consideration matters relating to the Congress.

DR. LUCIEN HOWE moved the appointment of a committee of three, of which the President was to be chairman, to confer with medical societies of other States with a view to some concerted action for re-establishing the National Board of Health. It was adopted.

Orbital Traumatism Resulting in Immediate Monocular Blindness from Fracture of the Optic Foramen; One Case of Blow over the Left Eye Causing Blindness of the Right Eye.—DR. PETER A. CALLAN read the paper, in which he described four cases of immediate monocular blindness following injuries to the head, which, from the symptoms, had evidently caused fracture at the foramen through which the optic nerve passed to enter the cranium. Autopsies, however, had not confirmed the existence of fracture in his cases (the patients being yet alive); but that such was the source of the blindness seemed more than probable from the nature of the injuries, the symptoms produced, and especially from the results of autopsies in similar recorded cases. Their number, however, had been comparatively small, only eighty besides his own, which fact led him to publish these. At first there were no ophthalmoscopic changes, but after two weeks or more the optic nerve showed a neuritis.

DR. LUCIEN HOWE put one case on record, that of a young man who got caught and hung on a butcher's hook, the point of which engaged under the orbital arch.

Methods of Advancing the Internal Rectus Muscle for Divergent Strabismus.—DR. LUCIEN HOWE, of Buffalo, read the paper. The method consisted in passing two sutures instead of one, as in Prince's method. The objection to the one suture, or Prince's, method, was that it caused a puckering and left a lump which, in young ladies particularly, was objectionable. The divergence, it should be remembered, should always be somewhat over-corrected.

The Danger of Milk of Tuberculous Cows.—DR. E. F. BRUSH, of Mount Vernon, did not exaggerate the danger of milk from tuberculous cows, but at the same time stated that in persons of depreciated health, it might at any time give rise to tuberculosis, and it was desirable, therefore, that milk should be obtained from cows known to be free from this disease. Doctors should make themselves better acquainted with the conditions under which cows were most likely to develop tuberculosis, with the methods of taking the temperature of cattle, the signs of tuberculosis, etc. Yet he had never been able to associate death in the infant directly with tuberculosis in the cow from which milk was obtained. But negative evidence of this kind should not count against known dangers. It was doubtful whether milk could be perfectly sterilized against the bacillus tuberculosis, at least by boiling, and attempts in this direction must depreciate its nutritive qualities.

Election of Officers.—*President.* Lewis S. Pilcher, of Brooklyn; *Vice-President.* H. L. Elsner, of Syracuse; *Secretary.* F. C. Curtis, of Albany; *Treasurer*, C. H. Porter, of Albany; *On Arrangements*, Bendell, Powell, Nellis; *By Laws.* Simmons, Wey, Curtis; *On Hygiene*, Laurence Johnson, Brush, Bell, Burr, Balch, Herman, Peck; *On Legislation*, Roosa, Daniel Lewis, Lewi; *Ethics*, Jacobi, Matheson, Glass; *On Prize Essays*, Fox, W. W. Potter, and Roe; *On Publication*, Curtis, W. W. Potter, Porter, Bailey; *Honorary Members*, McMurtry, of Louisville; Reid, of Cincinnati; W. E. B. Davis, of Georgia; Wright and Ross, of Canada. Numerous delegates were appointed to other societies.

Aluminium in Orthopedic Apparatus.—DR. S. R. MORROW, of Albany, presented a hip splint made of aluminium, which was about one-third the weight of the ordinary iron or steel instrument, and for this reason possessed marked advantages, especially in young patients. He thought the same material would come to take the place of the heavier metals in other orthopedic apparatus. It also showed little tendency to become tarnished.

DR. A. F. CURRIER had made some use of this metal in surgical instruments, where it possessed advantages because of lightness and cleanliness and resistance to antiseptics.

Biliary Calculus: Its Diagnosis and Treatment.—DR. C. W. DEBAUN read a paper with this title. In mild cases, heat and medicinal agents would probably give relief. Among solvents of stone the most efficient were the sulphate and phosphate of soda. Surgical aid should be given in painful and persistent cases

An abstract of a paper by Dr. Boardman Reid, of Atlantic City, entitled "The Teachings of Experience and Rational Therapeutics as to the Treatment of Pneumonia," was read by a member. Many other papers were read by title.

A vote of thanks was tendered Dr. Suiter for his able services as President.

After appropriate remarks by DR. SUITER, who introduced his successor, DR PILCHER, and expression of thanks by the latter for the honor conferred upon him by election to the highest and most responsible position of President, the Society adjourned.

Death from Chloroform.—The *Hospital Gazette* has stereotyped this heading, and the editors say that they have had no reason to regret the outlay. It is simply amazing to think of the apathy of the profession in the matter of the fatal effects of chloroform. How certain hospital surgeons can go on, day after day, and year after year, giving a dangerous anæsthetic when a much less dangerous one is at hand, is one of those things that it is difficult to understand.—*Montreal Medical Journal.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MR. ROSE'S LETTSOMIAN LECTURES ON THE SURGICAL TREATMENT OF TRIGEMINAL NEURALGIA — MADURA FOOT — ULCERATIVE ENDOCARDITIS OF PULMONARY VALVE — THROMBOSIS OF SPLENIC VEIN ASSOCIATED WITH INFARCTS IN THE SPLEEN.

LONDON, January 23, 1892.

IN the Lettsomian Lectures now in the course of delivery before the Medical Society of London, Mr. William Rose has selected for his subject, "The Surgical Treatment of Trigeminal Neuralgia." In his first lecture, after discussing the causes and classifying them, he gave some account of the pathological anatomy of the affection, referring to Professor Dana's recent paper in *The American Journal of Mental and Nervous Disease*. The leading symptoms of a typical case were then described. The lecturer then passed on to the subject of treatment and, after a brief allusion to medical treatment by drugs, hypnotism, etc., proceeded to discuss the various surgical procedures employed. The first and simplest method—neurotomy—was, he said, suggested by Albinus and Galen, and first carried out on a branch of the fifth nerve by Schlichting and Maréchal about one hundred and fifty years ago. The results of the earlier operations, however, whether neurotomy or neurectomy, were not satisfactory. In 1860, Nussbaum, of Munich, accidentally discovered the value of nerve-stretching as a means of treatment. It was now practically admitted by almost all surgeons that nerve-stretching should be retained as a means of dealing with neuralgia of mixed nerves only, and it was undoubtedly beneficial in some such cases. But with the fifth nerve, which was almost entirely sensory, no permanent relief could be expected from the operation, and neurectomy was infinitely to be preferred. Probably in all cases of neurectomy a certain amount of stretching of both central and peripheral ends accompanied the manipulations necessary to free the trunks, and it was an open question whether such traction had any beneficial effect or otherwise. It was now a tolerably well-established fact that central changes could result in those instances where the nerves passed directly through short, straight canals to the central organ. The lecturer said that ligature of the carotid artery had been employed as a means of treatment but, as one case thus treated had ended fatally, he would exclude it, except as a last resort. It might be employed if pain recurred after removal of the Gasserian ganglion.

The second lecture was devoted to discussing the various operations on the different branches of the fifth nerve. Where neurectomy of the first, or ophthalmic, division of the nerve was necessary, the orbit must, said the lecturer, be opened by division of the orbito tarsal ligament, the orbital fat depressed by a spatula, and the nerve, freed from its connections, lifted on a blunt hook; it should be divided as far back in the orbit as possible.

In the case of the second, or supra maxillary, division all that was needed to expose the foramen was a transverse incision extending through the orbicularis and separating its fibres. By a careful dissection the nerve could be seen emerging from the foramen and half an inch of it could be removed. (The lecturer condemned the subcutaneous or submucous method of division formerly in vogue, in which the surgeon simply passed a tenotome into the foramen and twisted it round.) In order to expose and excise larger portions of the nerve, three distinct plans had been suggested and practised, which might be named respectively, the *orbital*, the *antral*, and the *pterygo maxillary*. Several different operations had been suggested under the first of these headings, notably Langenbeck's and Wagner's. In the former the infra-orbital foramen was first exposed by a transverse incision, and the nerve freed at its point of exit and secured by forceps. Dieffenbach's tenotome was then entered close to the outer canthus, just below the outer palpebral ligament and passed backward along the anterior border of the pterygo maxillary fissure, which was crossed by the nerve about an inch behind the orbital margin. The knife should be kept close to the bone and not inserted too far, lest the spheno-maxillary fossa be entered and serious hemorrhage result. By withdrawing the knife carefully and keeping the edge closely applied to the bone the nerve could be divided as it entered its canal. Traction or torsion upon the peripheral end would enable the whole length of the nerve to be removed and the dental branches given off in its course to be torn through. Malgaigne made a similar preliminary incision, but divided the nerve as it entered the bone by passing a tenotome along the floor of the orbit. The great objection to both of these proceedings was the hemorrhage which resulted from the division of vessels in a situation inaccessible to ligature and the uncertainty which attended the use of a knife at such a depth. Moreover, the nerve was divided in front of Meckel's ganglion, and probably of the posterior dental branches. With a view of meeting some of these conditions Wagner introduced a different method, viz.: he raised the orbital contents from an incision running transversely below the orbital margin, laid open the infra-orbital canal with a chisel, separated the artery from the nerve with a special aneurism needle having a lateral curve, and divided the nerve behind the origin of the dental branches. Professor Horsley's plan of operating was practically the same as Wagner's; he stitched the eyelids together as a preliminary precaution.

The lecturer then discussed the antral method, a method, he said, which was devised and originally introduced by Carnochan, of New York, in 1858, in order to remove Meckel's ganglion as well as the nerve. Twenty-two cases of the operation were collected and brought before the Royal Medical and Chirurgical Society in 1884, by Chavasse, but only three of these seemed to have derived permanent benefit, so the results of the operation were not encouraging. Of five cases similarly treated by Mr. Treves, the neuralgia recurred in four cases, while the fifth patient died of cancer within six months. Von Bruns and Otto Weber had introduced a modification of this operation. The third means of dealing with this division of the fifth nerve, viz., the pterygo-maxillary operation, was originally suggested by Professor Lücke, and subsequently modified by Professors Braun and Lossen. The advantages of this operation were that the cicatrix would be less obtrusive on looking at the patient full-face, and the hemorrhage would be less, in that the internal maxillary artery could be secured before the fossa was opened; moreover, the antrum was not opened, and the risk of septic contamination of the wound considerably diminished.

After describing the surgical anatomy of the third, or inferior maxillary, division of the fifth nerve, Mr. Rose remarked that the inferior dental nerve could be exposed in three situations—at its exit from the mental foramen, in the dental canal, and above the dental canal. The lecturer said he always had recourse to the higher operation, as the results of the other two were unsatisfactory. There were three methods of performing it, viz., the intra-buccal, the retro-maxillary, and the trans-maxillary. The latter operation promised to be the most effectual, and was, perhaps, that most generally adopted in the present day; it was usually accomplished by deepening the sigmoid notch.

The want of success attending these methods had led surgeons to extend the scope of their operations to the base of the skull, hoping by division of the nerves at their points of emergence, and by a more extensive removal of the nerve trunks, to obtain results of a more permanent character. Three different plans had been suggested and practised for reaching the foramen ovale, viz., 1, Pancoast's method, with various modifications suggested

by Salzer, Krönlein, etc.; 2, the Lücke-Sonnenburg method; 3, the plan of deepening the sigmoid notch, as practised by Mr. Horsley, himself, and others. The lecturer said he considered the latter the best method, not only for reaching the foramen ovale, but also for removing the largest extent of the trunks. He described this operation in detail, and said he had performed it repeatedly within the last seven or eight years with comparative ease. and with relief to the patient for the time being; he confessed, however, that in by far the majority of cases the pain recurred at the end of a year or two, necessitating the further measures which he would detail in his next lecture.

At the last meeting of the Pathological Society, Mr. A. A. Kanthack showed a hand and foot affected with fungoid disease (Madura disease); they had both been amputated by Dr. Browning, of Madura. Dr. Chaplin read a paper on a specimen of ulcerative endocarditis of the pulmonary valves. Dr. Rolleston showed a specimen of thrombosis of the splenic vein, associated with infarcts in the spleen which had some features of interest, viz., the association of complete thrombosis of the splenic vein with death of limited portions of the spleen, so as to produce the appearance of infarcts due to embolism of the splenic artery, and the fact that these infarcts were anæmic, and not hemorrhagic, as from the venous stasis would have been expected.

FORMING THE CHARACTER OF THE UNBORN INFANT.

To the Editor of the Medical Record.

Sir: It may seem rather late to again bring up the subject of maternal impressions. But there is a side to this question which I have not seen touched upon. If the reader of th s ever indulges in novels to any great extent, he has probably read, or at least heard of a novel, which only a few years ago attracted considerable criticism, both friendly and adverse.

The novel I refer to is "Mal Moulée." In all the criticisms I ever read the main subject matter, maternal impressions, seemed to meet with little comment. In describing the characters of the heroine and her schoolmate friend, there was ascribed to each certain governing characteristics, exalting and beautifying the life of the one and finally wrecking that of the other, and which seemed to be largely due to maternal impressions. The authoress, I think, sought to present her own and her mother's views upon the subject, thoroughly believing her own sweet rhyming to be the result largely of such prenatal forces.

The authoress's mother upon one occasion imparted to the writer her opinion in the premises, supplementing them by the following illustrations. The words and sequence of pregnancies are, so near as I remember them, her own.

"Now, doctor, I do believe in maternal impressions, and for very good reasons, as I'll tell you. When I was first pregnant I wished my offspring to be a musician. So during the whole period of that pregnancy I settled my whole mind on music, attending every musical entertainment I possibly could. I had my husband, who has a fine violin, and who is a good violinist, play for me by the hour. When the child was born it was a girl, which grew and prospered, and finally became, as you've undoubtedly heard, an elegant musician, a first-class one.

"During the period of my second conception I wished the offspring to be an editor, and I bent my whole mind to the attainment of such result. I read the papers almost continuously, paying especial attention to the leading editorials of such of the great periodicals and dailies of that time as I could lay hands on, even neglecting some of the smaller household duties in my efforts to attain the desired results. The child being a male, I expected my hopes to be realized. And, although doomed to disappointment, everyone who reads his letters says he ought to have been an editor.

"When I was carrying my third child, I put my whole energies to bring forth a poet. I read poetry, doted on it, lived in it, and when, during waking, unable to read it, I thought of it, and when asleep dreamed of it. And, Byron being my favorite poet, I devoted to him more than a due proportion of my reading. and, doctor, my daughter is a poetess, and her poems partake so much of the noble grandeur of Byron that her critics have often asked her why she didn't copy someone else part of the time.

"When I became next pregnant my desires had been satisfied, and I didn't care what he was, and he is."

While not convinced, I had to acknowledge that she had the weight of evidence against me. For, as she had said, in regard to those facts with which I was not personally cognizant, I had heard her assertions corroborated by those who were old acquaintances. Was she right or wrong? I give it up. But of this much I feel assured, that anyone, especially a prospective mother, can, by a careful perusal of "Mal Moulée," do herself no possible damage and may place herself in the way of vastly improving that portion of the world she is destined to repopulate.

F. W. Moffitt, M.D.

FAVORITISM AT THE NEW YORK ACADEMY OF MEDICINE.

To the Editor of the Medical Record.

Sir: At the risk of harping upon an outworn theme, I would venture to add my approval of the various criticisms which have recently appeared in your columns regarding the management of discussions at the Academy of Medicine. Dr. Amidon's protest, although rather severe, was just. It is a fact that the discussions are practically open only to a favored few. As one of the younger generation of gynecologists, I am obliged to acknowledge that the gentlemen who devote themselves to pelvic affections are among the principal offenders. The curious reader will find that all papers on this subject which have been read during the past ten years. have been discussed by not over a dozen or fifteen gynecologists, whose ideas have been re-vamped until they have become quite threadbare. These gentlemen are veteran speakers, accustomed to lecture to medical students, their knowledge is supposed to be at their finger-ends; yet they invariably take twenty minutes to say what could be condensed into five. Herein lies the injustice of the present system—not so much the fact that the same gentlemen are always "billed to appear." but that they are always allowed as much time as they wish in which to present their twice-told tales, while those who follow them are summarily cut short. Personally, when I am asked to discuss a paper and find that I am to be preceded by several of these "war-horses of debate" (as Dr. Amidon wittily describes them), I invariably absent myself, knowing that, if called upon at all, I shall be grudgingly allowed three or four minutes at the tail-end of the meeting. This is the age for young men. They cannot and will not be "sat upon," either in the practice of medicine or in scientific discussions. Gynecologist.

ALLEGED MAMMÆ ERRATICÆ.

To the Editor of the Medical Record.

Sir: I have just read Dr. McGillicuddy's paper on "The Mammæ and their Anomalies," in your issue of October 10, 1891. During the last twenty-five years an immense number of cases of supernumerary mammary structures have been recorded, and the literature of the subject has become quite prodigious. Several of Dr. McGillicuddy's cases of alleged mammæ erraticæ are, however, so *bizarre*, and altogether unparalleled by anything of the kind pre-

viously published, that I think they ought to be very critically examined before they are definitely accepted as being what they purpose to be—true supernumerary mammæ. So many fallacies are possible—nay, probable—in the diagnosis of such anomalies, that we ought not to accept alleged unique cases without most conclusive evidence as to their real nature. Now, it is just in this respect that several of Dr. McGillicuddy's cases are, I think, open to grave objection. For instance, in Case IV. (Fig. 5) he has described an instance of alleged mamma erratica in a situation where such an anomaly has never before been observed, *i.e.*, on the lateral aspect of the thorax (R.) over the eighth rib. The only evidence adduced in favor of the tumor being a supernumerary mamma is (1) that it is said to have been noticed at birth; (2) that she had pain in it at the menstrual period. Nothing is said as to nipple or areola. In establishing the identity of such a tumor with a supernumerary mamma, this evidence has of course no weight. Again, in Case VI. (Fig. 7) we have a man with a tumor at the back of the left thigh, just below the gluteal fold, and we are told that this also is a supernumerary mamma. We ask why? The only answer is because (1) his sister states it was first noticed at birth; (2) it has a lobular structure like the normal breast of a young woman. There was no areola or nipple.

Considering the frequency with which congenital angiomata, lipomata, and fibromata have been mistaken for supernumerary mammæ, such evidence is of course absolutely worthless for making the differential diagnosis. Never having seen the patients myself, I can offer no opinion as to the nature of the tumors in these cases, I must simply content myself with pointing out that the evidence adduced in favor of their being supernumerary mammæ is altogether inadequate. On the grounds of general morphology also, there is much to be said against the acceptance of these cases as true mammæ erraticæ, but I cannot enter on that aspect of the question in this brief letter. I must refer those who care to pursue the matter further, to my essay on "Polynestism with Special Reference to Mammæ Erraticæ, and the Development of Neoplasms from Supernumerary Mammary Structures," in the *Journal of Anatomy and Physiology*, January, 1891, p. 225.

Yours truly,
W. Roger Williams, F.R.C.S. Eng.

Preston, January 20, 1892.

THE PERINEUM; HOW TO SAVE IT?

To the Editor of the Medical Record.

Sir: In your issue of December 5, 1891, Dr. N. W. Rand has an article on the above subject, which I think calls for some notice. Drs. Tucker and Gasser have, I see, in your issue of December 19th, already subjected the paper to well deserved criticism, demonstrating how the method of saving the perineum advocated by Dr. Rand is one that must appeal to all physicians endowed with that most important essential for a medical man, commonsense. Although my object in writing this is not specially to deal with Dr. Rand's method, seeing that the two doctors above mentioned have already proven it to be no "lost art," yet I think the following case will show how useful it may be at times. About eight years ago I was summoned one dark night to attend a woman in labor, living in an almost inaccessible spot. On arrival I found the patient, a young black woman, about fourteen years of age, in what may truly be called a hovel. By the aid of an improvised kerosene lamp I began my examination, when to my surprise I found the young woman the possessor of a vagina into which I could only with ease insert one finger. This was due to narrowness not only of the orifice, but the whole length of the vagina. I involuntarily said to myself, "Something will have to give way to night before a child can come into the world." Not being green, however, to the work, and knowing the dilating power of the organ, I set to work by the method mentioned by Dr. Rand, and after about an hour's work, had the satisfaction of seeing the head distend the perineum; when resorting to Goodell's method, I was much relieved at seeing a child of fair size born into the world, leaving behind an intact perineum. Certainly by no other means than the two methods combined could the child have been born without the mother's parts being badly lacerated. So much, then, for the method advocated by Dr. Rand. I come now, however, to the gist of my communication. Dr. Rand, to me, is astray as to the application of Goodell's method. The method is not, although often described in that way, the drawing of the whole perineal body over the head with each pain, but only when the head is emerging. Applied at each pain, it would certainly be disagreeable to both patient and physician, but when done at the right time I fail to see its objection on that score to either party concerned. Goodell's method is one that I have used for years, with, I must confess, very great success; and such a result is, I believe, claimed by all who practise it. That being the case, the question is, what is the *rationale* of its success? To answer that, let us see what takes place when the head is emerging in, say, the occipito-anterior position. In the words of Lusk, "So soon as the bi-parietal diameter passes the tense border of the vulva, the perineum retracts rapidly over the face, and the expulsion of the head is completed." It is during this period, he says, that laceration is most liable to occur. Let us see why it should be so. It is because the strain commencing at the passing of the bi-parietal diameter, is continued by the expelling force applied to the rapidly extending head. Now, there can be no method which can prevent the bi-parietal strain, but the aim of all should be to render the duration of that strain as short as possible. That is what Goodell's method does, and it accomplishes it in a threefold way: 1. When the fingers, hooked into the anus, bring the perineum forward, an amount of force is applied to the head, preventing a too rapid extension. 2. By thus pulling the perineum upward and forward, the opening is applied to the head, in that position, through which it can most readily pass; and 3. By putting the perineum on the stretch the nerves are in a measure paralyzed and the parts relaxed. The above is a rude explanation of the *modus operandi* of Goodell's method, as understood by me. Should any of your readers take exception to it, I beg them to try and put me right where wrong. It is certainly a question worth threshing out.

Although Dr. Rand by this has learned that the method advocated by him is no "lost art," yet he deserves thanks for bringing it forward, if only in the interest of beginners, seeing that it is not mentioned in the text-books.

I am, Sir,
Yours obediently,
R. F. Licorish, M.D.

Bridgetown, Barbadoes, West Indies, January 3, 1892.

THE NON CONTAGIOUSNESS OF LEPROSY.

To the Editor of the Medical Record.

Sir: In your number of the Record of January 23d appears an account of a paper with the above title read at the County Medical Association by Dr. Bulkley, about which I cannot refrain from saying a word, especially as I feel sure you will print what I have to say, since reading in the same issue your excellent editorial which takes the opposite ground and the one which it seems to me every thoughtful man should take. It is highly gratifying to me that the Record takes the position it has, for in order to accomplish any reform in this direction just such authority is needed. Legislators will look to the leaders in medical thought for the warrant in whatever they undertake, and for this reason it distresses me to witness the stand taken by one of the leaders in dermatological thought. If, however, the Record's account of the paper is full and accurate,

it should not exert any great influence, for it brings forward no new nor strong arguments, presents no facts to show the non-contagiousness, but deals simply with negative evidence and generalities. Leprosy is as unnecessary in this country as it is undesirable. It should be stamped out now as a matter of public economy, and its suppression not delayed until millions will be required where now dollars will do the work. The author apparently admits that the disease is due to a bacillus, and that this bacillus is the same the world over, and that "where it has apparently been absent there probably has been some failure in the technique," and this being so it is not impossible for the disease to arise by contagion, but that the degree of contagiousness "must be extremely small."

Now, no one pretends to claim that the degree of contagiousness is anything else than small. And here is the weak point in Dr. Bulkley's argument. It reminds me of the young servant girl whose mistress learned that while in her last place she had borne a child out of wedlock, and accused her of it. "Yes," pleaded the girl with tears in her eyes, "I did have a baby, but it was a very little one."

The writer is further quoted as saying that contagion could not apply to certain instances which had come under his observation, having seen several cases of leprosy developing in this country in patients who had never come in contact with any leprous person. How can such a statement be made? How many physicians, even, can recognize a leper on the street?

If an unusual weed springs up in Dr. Bulkley's back yard, doesn't he look over his neighbor's fence expecting to find the same variety of plant growing there, and doesn't he know, in case he fails to find what he expects, that an ill-wind has blown the seed of the plant there, or that a bird has dropped it in flying overhead; or, more probably, that when he had the soil fertilized the seed was carried in with the manure, and that the parent plant is to be sought in a corner of the stable-yard.

Now, the reason Dr. Bulkley sits in his study and carries out this line of thought is because he knows that the seed of that particular weed is the same the world over, is always found, and when planted produces the same kind of weed, if it produces anything.

With the number of lepers in New York and vicinity allowed to go about at will one can never say when or where or by whom they are met.

The talk about contagion is utterly futile to my mind. It practically makes no difference whether the disease is contagious "in the ordinary acceptation of the term" or not. If, as Dr. Bulkley admits, there is strong reason to suspect that the bacillus may be introduced into the system by way of food, and that "there is evidence that the disease might, under favorable conditions, be transferred from one person to another," then how, I ask, can he consistently add to his conclusions "there is no necessity for segregation." How does the bacillus get into food if not from a subject of leprosy?

What difference does it make by what name you call it if one person, having the disease, is in a position to transmit it to another, or why is such a person not as much a source of danger as though the one man in five thousand who is going to get the disease from him does it by drinking from the same cup or shaking the leper by the hand. An effort is now being made to secure some legislation in the matter and it is important that no misleading views should go forth. Let us drop the word "contagion" in reference to leprosy and speak of it, as most of us believe it, and some of us think we know it to be, a dangerous but preventable disease.

CHARLES W. ALLEN, M.D.

Died from Fasting.—A man who had been fasting some forty days at a museum in this city died from the effects of his effort.

THE DOSE PARALDEHYDE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD for January 2, 1892, J. B. Mattison gives me a reprimand for having in a previous issue put the maximum dose of paraldehyde at one drachm and for having prescribed only fifteen minims at a dose.

I can only reply that my idea of the maximum dose of paraldehyde is not original. As stated in a previous letter, it was borrowed from the last therapeutic productions of the following well-known authorities, viz., S. Ringer (twelfth edition), H. C. Wood (seventh edition), Hobar A Hare, C. Cauquil, J. C. Wilson (Pepper's "System o Medicine"), "Annual of the Universal Medical Sciences, for 1891," "Year-Book Treatment" (Lea Bros.). I also consulted files of the MEDICAL RECORD and *Therapeutic Gazette* for past three years. Nowhere did I find a record of a single dose administered that exceeded 90 minims. Dujardin-Beaumetz states that he gives 30 grains, Desnos says emphatically that "if hypnotic effects are not obtained with from 45 to 60 grains it is useless to push it" (paraldehyde). W. H. Flint reports, in the *Therapeutic Gazette*, January, 1891, thirty-five cases in which he had used paraldehyde in doses of 60 to 90 minims. He found that larger doses produced paralysis of the spinal cord, abolished reflex action, and finally arrested respiration. With such facts in mind it is not remarkable that some alarm should be felt over a dose of 10 grammes. Paralysis of the spinal cord and stoppage of respiration are very ugly symptoms in private practice, especially if a comparatively new remedy has been given in doses rather larger than is sanctioned by authors of treatises on therapeutics.

Regarding the prescribed dose, the doctor is mistaken. I prescribed 10 grammes paraldehyde with 20 grammes of sirup (not 30 as incorrectly printed). The tinned sheet-iron teaspoon in use among the poor holds from 6 to 7 grammes. The whole amount prescribed contained at most not to exceed five such teaspoonfuls. My experience with paraldehyde is not extensive, but it has been successful, especially in insomnia of alcoholism. I have, however, never ventured to give more than 4 grains at a dose, and I have in second instances succeeded with two or three grains.

J. NOER, M.D.

SLOUGHTON, WIS., January 20, 1892.

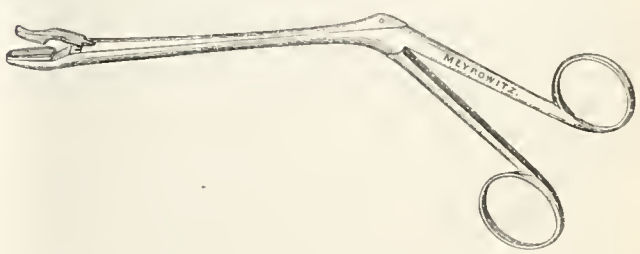
New Instruments.

A NASAL CLIPPER.

BY ROBERT C. MYLES, M.D.,

ASSISTANT SURGEON TO NOSE AND THROAT DEPARTMENT NEW AMSTERDAM EYE AND EAR HOSPITAL; LECTURER IN NOSE AND THROAT DEPARTMENT, NEW YORK POLYCLINIC.

I OFFER a little instrument, which I have named the Nasal Clipper. It is made after the manner of alligator nasal forceps. The shaft is $3\frac{3}{4}$ inches long, and the handle 3 inches. There is a strong cutting-punch for-



ceps at the end, 2 millimetres ($\frac{1}{12}$ inch) wide, by 6 millimetres ($\frac{1}{4}$ inch) long. A complete set is composed of three pairs—two, right and left, each cutting on one side only, and one pair with sharp cutting edges on both sides.

It was designed to remove tissue from the nasal cavities in a definite way, from almost any part, without injuring the adjacent membranes.

In skilful hands it will remove the inferior hypertrophied portion of the middle turbinated body without doing harm to the bone, periosteum, or mucous membrane of the ethmoid. I have found it extremely useful for removal of adhesion of external and internal walls; small fin-like ridges of cartilage, especially along the suture between vomer and perpendicular plate of ethmoid, carious bone, polyp pedicles, and wherever I wanted to excavate a spot on the external wall, leaving a definite circumference.

They were made for me by Mr. E. B. Meyrowitz, New York. After testing, I commend their practical usefulness.

25 West Thirty-sixth Street.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 6, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	4
Scarlet fever	206	24
Cerebro-spinal meningitis	2	3
Measles	141	16
Diphtheria	111	18
Small-pox	8	1
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Laparotomy on an Infant One Day Old.—Dr. Salmon reports, in the *Gazette des Hôpitaux* of November 12, 1891, a case of congenital umbilical hernia of large size, in which it was evident that treatment by compression would inevitably result in death. It was therefore decided to perform laparotomy, replace the bowel, and draw together the edges of the abdominal defect by sutures. This was done by M. Maunoury on the day after the child's birth, and was eminently successful. A similar case was reported not long ago in the *New York Medical Journal*.

Physicians' Signs.—The fashion, in various cities in Europe, as to the door-plates and signs of physicians is interesting in its variety. In London a large door plate of brass or silver is the thing. In the West End of that city doctors seem to live together, and one may see two or three in the old-fashioned, very neat English-basement houses that are to be found in such great numbers in Harley Street, Brooke Street, George Street, Grosvenor Square, and so on. In Brussels the outside of the house is sometimes decorated *à la* New York, but generally with more taste. There professional men do not hesitate to announce their specialty. In Berlin, where a celebrated man may be one or more flights up, a porcelain plate neatly inscribed with black letters, sometimes with the specialty, and always with the office hours, is in good form. In Paris there is such an absence of signs or door-plates that it is in many instances difficult to know that you are at the right house, so modest or negative are the indications. In Paris, too, distinguished specialists sometimes live very high up, in great apartment houses without elevators. But some of the great Paris physicians live magnificently in town, and have fine country places as well. Along the Quai d'Orsay and the Quai Voltaire are noble houses, now used for business and other purposes, and formerly occupied by Nélaton and Trousseau. But the great men of the present in Paris live on the other side of the Seine. Why they do it, it is hard to say, for everything is very inviting still in the skirts of the Latin Quarter; and in the old Quarter itself, the new boulevards have destroyed all the intricacy and griminess of the region. Philadelphia and Boston outdo New York in the magnitude and splendor of door-plates and office-signs. It is doubtful if they are ever of any particular use, except for those who are looking for a doctor in an emergency, and a very simple indication would be as well as the great sprawling tin, or black marble, or brass affairs that disfigure many a good-looking house.

Cremation in Berlin.—The city of Berlin is about to erect a crematory in the Friedrichsfeld cemetery, where the bodies of unclaimed paupers as well as the remains of the dissecting-room are to be burned. There are about a thousand bodies dissected every year. To popularize the practice of burning the dead, the Berlin Society for Cremation has petitioned the Parliamentary Commission on the Civil Code that the choice between burial and burning be granted hereafter to every German citizen.

The Association of Ulcer of the Stomach and Cardiac Disturbances.—At a recent meeting of the Medical Society of London, Dr. Ord read a paper in which he drew attention to the not infrequent association of gastric ulcer with cardiac disturbance. In a large number of patients with well-marked symptoms of gastric ulceration, he had observed an extension upward on the left side of the sternum of the area of cardiac dulness, a shifting of the apex-beat upward and to the left, friction sounds, mitral systolic murmurs transmitted to the axilla, and accentuation of the second sound over the pulmonic area. The patients were, it is true, anæmic, but anæmic murmurs are usually more fugitive, and in simple anæmia, too, the pulmonary second sound is not accentuated. The speaker thought it possible, however, that, as a part of the nerve disturbances of anæmia, there might be tension in the pulmonary artery, thus diminishing the circulation in the lung (which would then shrink and so occasion increase of the area of cardiac dulness), and increasing pressure in the artery. He suggested that the gastric ulceration and the cardiac changes might be due to a common factor, and that this might be some disturbance of the pneumogastric nerve. He pointed out that ulcers of the stomach more nearly resembled in their nature ulcers arising from other nerve disturbances, such as herpes, than those caused by embolism or thrombosis of an artery.

Ununited Fractures in Children.—A meeting of the Medical and Chirurgical Society of London, in December last, was devoted to discussing the subject of "Ununited Fractures of the Long Bones in Children." Mr. D'Arcy Power introduced the discussion by a paper in which he gave an analysis of sixty-three cases. He remarked that the subject had been almost entirely neglected until the publication of Sir James Paget's paper in his work entitled "Studies of Old Case Books." Mr. Power said the statistics he had collected entirely bore out Sir James Paget's conclusions. The results of treatment were most unsatisfactory. Out of the 63 cases, bony union was obtained in only 6, and in 7 cases the patient was relieved, but in 36 cases no improvement whatever ensued on treatment. The author believed that ununited fractures were becoming more common, at least in England, though he pointed out that in France non-union was very rare—not in children only, but in adults. He remarked that the ease with which plaster of Paris could be applied was one of the dangers in using it. If the child were carefully watched, nothing could be better; but in plaster there was great liability of a child's leg shrinking and movement could then occur inside the case.

PRESENT PROBLEMS IN EVOLUTION AND HEREDITY.

THE CARTWRIGHT LECTURES FOR 1892.

BY HENRY FAIRFIELD OSBORN, Sc.D.,

DA COSTA PROFESSOR OF BIOLOGY IN COLUMBIA COLLEGE, NEW YORK.

IN the past decade of practical research and speculation in biology two subjects have outstripped in interest and importance the rapid progress all along the line. These are, first, the life history of the reproductive cell from its infancy in the ovum onward, and second, the associated problem of heredity, which passes insensibly from the field of direct observation into the region of pure speculation.

As regards the cell it was generally believed that the nucleus was an arcanum into the mysteries of which we could not far penetrate; but this belief has long been dispelled by the eager specialist, and it is no exaggeration to say that we now know more about the meaning of the nucleus than we did about the entire cell a few years ago. At that time the current solution of the heredity problem was a purely formal one; it came to the main barrier, namely, the relation of heredity and evolution to the reproductive cells, and leapt over it by the postulate of Pangenesis. The germ-cell studies of Balfour, Van Beneden, the Hertwig brothers, Weismann, Boveri, and others, have gradually led us to hope that we shall some day trace the connection between the intricate metamorphoses in these cells and the external phenomena of heredity, and more than this, to realize that the heredity theory of the future must rest upon a far more exact knowledge than we enjoy at present of the history of the reproductive cell both in itself and in the influence which the surrounding body cells have upon it.

These advances affect the problem of life and protoplasm, whether studied by the physician, the anthropologist, or the zoölogist, thus concentrating into one focus opinions which have been formed by the observation of widely different classes of facts. As each class of facts bears to the observer a different aspect and gives him a personal bias, the discussion is by no means irenical, and it is our privilege to live through one of those heated periods which mark the course of every revolution in the world of ideas. Such a crisis was brought about by the publication of the theory of Darwin, in 1858, and after subsiding, has again been roused by Weismann's theory of heredity, published in 1883.

This is the situation I have ventured to present to you as Cartwright lecturer, not, of course, without introducing some conclusions of my own, which have been derived from vertebrate palæontology, but which I shall direct mainly upon human evolution.

So far as theories need come before us now, remember that Lamarck (1792) attributed evolution to the hereditary transmission to offspring of changes (acquired variations) caused by environment and habit in the parent. Darwin's latest view was that evolution is due to the Natural Selection of such congenital variations as favored survival, supplemented by the transmission of acquired variations. Weismann denies the transmission of acquired variations, or characters, entirely, and attributes evolution solely to the natural selection of the individuals which bear the most favorable variations of the germ or reproductive cells. We must, therefore, clearly distinguish between "congenital variations" which are part of our inheritance and "acquired variations" which are due to our life habits; the question is, Are the latter transmitted?

At the outset I would emphasize the extreme complexity of evolution by a few words upon Variation, or in terms of medical science, upon anomalies.

When we speak of a part as "anomalous" we mean that it varies at birth from the ordinary or typical form—it may be minute, as the small slip of a tendon, or large, as the addition of a complete vertebra to the spinal column. Wood has found that in the muscular system alone there are nine anomalies in the average individual. It is clear that the evolution of a new type, so far as the muscular system is concerned, must consist in the *accumulation of anomalies in a certain definite direction by heredity*. Thus the anomalous condition of one generation may become the typical condition of a very much later generation, and we observe the paradox of a typical structure becoming an anomaly and an anomalous structure becoming typical; for example, the supracondylar foramen of the humerus was once typical, it is now anomalous; the retardation in development of the wisdom tooth was once anomalous, it is now typical.

The same principle applies to races which are in different stages of evolution; an anomaly in the white, such as the early closure of the cranial sutures, is normal in the black. Now the deductions of the Weismann school of evolutionists seem to be founded upon the principle "*de minimis non curat lex;*" that we need only regard such major variations as can, *ex hypothesi*, weigh in the scale of survival. Against this I urge that we must regard the evolution of particular structures, the components of larger organs, the separate muscles and bones for example, for the very reason that while in some cases they play a most humble *rôle* in our economy we can prove beyond a doubt that they are in course of evolution. Minor variations in foot structure, which are possibly of vital importance to a quadruped whose very existence may depend upon speed, sink into obscurity as factors in the survival of the modern American.

The evolution of man in the most unimportant details of his structure promises, therefore, to afford a far more crucial test of the Lamarckian *vs.* the pure Natural Selection theory, than in the domain of his higher faculties, for the reason that Selection may operate upon variations in mind, while it taxes our credulity to believe it can operate upon variations in muscle and bone. This is my ground for selecting the skeleton and muscles for the subject of the introductory lecture. Nevertheless, let us review variation in all its forms in human anatomy before forming an opinion. Let us remember, too, that congenital and acquired variations are universal as necessities of birth and life; they are exhibited in the body as a whole—in its proportions, in the components of each limb, finally in the separate parts of each component, as in the divisions of a complex muscle. Thus the possibilities of transformism are everywhere. What is the nature and origin of congenital variations? Their causes? Do they follow certain directions? Do they spring from acquired variations by heredity? These are some of the questions which are still unsettled

But striking as are the anomalies from type, the repetitions of type as exhibited in atavism and normal inheritance are still more so, and equally difficult to explain. Therefore our theory must provide both for the observed

laws of repetition of ancestral form and the laws of variation from ancestral form, as the pasture-land of evolution. Add to these, that for a period in each generation this entire legislation of nature is compressed into the tiny nucleus of the fertilized ovum, and the whole problem rises before us in the apparent impregnability which only intensifies our ardor of research.

LECTURE I.

The Contemporary Evolution of Man.

"La vraie science et le vraie étude de l'homme, c'est l'homme."—Charron.

The anthropologists and anatomists have enjoyed a certain monopoly of *Homo sapiens*, while the biologists have directed their energies mainly upon the lower creation. But under the inspiring influences of the Darwinian theory these originally distinct branches have converged, and as man takes his place in the zoölogical system, comparative anatomy is recognized as the infallible key to human anatomy.

For our present purpose we must suppress our sentiment at the outset and state plainly that the only interpretation of our bodily structure lies in the theory of our descent from some early member of the primates, such as may have given rise also to the living Anthropoidea. This is also the only tenable teleological view, for many of our inherited organs are at present non-purposive, in some cases even harmful, as the appendix vermiformis.

From the typical mammalian stand point man is a degenerate animal; his senses are inferior in acuteness; his upright position, while giving him a superior aspect, entails many disadvantages, as recently enumerated by Clevenger,[1] for the body is not fully adapted to it; his feet are not superior to those of many lower Eocene plantigrades; his teeth are mechanically far inferior to those of the domestic cat. In fact, if an unbiassed comparative anatomist should reach this planet from Mars he could only pass favorable comment upon the perfection of the hand and the massive brain! Holding these trumps, man has been and now is discarding many useful structures. I refer especially to civilized man, who is more prodigal with his inheritance than the savage. By virtue of the hand and the brain he is, nevertheless, the best adapted and most cosmopolitan vertebrate. The man of Néanderthal or Spy, with retreating forehead and brain of small cubic capacity[2] was limited both in his ideas and his powers of travel, yet he was our superior in some points of osteological structure. But the period of Néanderthal was recent compared with that in which some of our rudimentary organs were serviceable, such as the vermiform appendix or the panniculus carnosus[3] muscle. These rudiments, in turn, are neogenetic when we consider the age of the two antique sense organs in the optic thalamus, the remnants of the median or pineal eye and the pituitary body, both of which were undoubtedly present, and probably useful, in the recently discovered Silurian fishes!

I mention these vestiges of some of the first steps in creation to illustrate the extraordinary conservative power of heredity (which is even more forcibly seen in our embryological development), partly also to show how widely our organs differ in age. Galton has compared the human frame to a new building built up of fragments of old ones; extend this back into the ages and the comparison is complete.

Development, Balance, Degeneration.—It is probable that none of our organs are absolutely static and that the apparent halt in the development of some is merely relative, as where a fast train passes a slow one. The numerous cases of arrested evolution in nature are always connected with fixity of environment, an exceptional condition with man, and we have ample evidence that some organs are changing more rapidly than others.

Adaptation to our changing circumstances is mainly effected by the simultaneous development and degeneration of organs which lie side by side, as in the muscles of the foot or hand; in terms of physiology, we observe the hypertrophy of adaptive organs and atrophy of inadaptive or useless organs. This compensating readjustment, whereby the sum of nutrition to any region remains the same during redistribution to its parts, may be called metatrophism. It is the gerrymander principle in nature.

In practical investigation it is very difficult in many cases to determine whether an organ is actually developing or degenerating at the present time; although its variability, or tendency to present individual anomalies, indicates that some change is in progress. I may instance the highly variable peroneus tertius muscle (Wood). The rise or fall of organs is so constantly associated with their degree of utility, that in each case the doubt can be removed by a careful analysis of the greater or less actual service rendered by the part in question. Apart from the question of causation, it is a fixed principle that a part degenerating by disuse in each individual will also be found degenerating in the race.

Degeneration is an extremely slow process; both in the muscular and skeletal systems we find organs so far on the down grade that they are mere pensioners of the body, drawing pay (*i.e.*, nutrition) for past honorable services without performing any corresponding work—the plantaris and palmaris muscles for example. Of course an organ without a function is a disadvantage, so that the final duty of degeneration is to restore the balance between structure and function, by placing it *hors de combat* entirely. One symptom of decline is variability, in which the organ seems to be demonstrating its own uselessness by occasional absence. As Humphrey remarks: "The muscles which are most frequently absent by anomalies are in fact those which can disappear with least inconvenience, either because they can be replaced by others or because they play an altogether secondary *rôle* in the organism." The stages downward are gradual; the rudiment becomes variable as an adult structure, then as a fœtal structure; the percentage of absence slowly increases until it reappears only as a reversion; finally the part ceases even to revert and all record of it is lost. This long struggle of the destructive power of degeneration, which you see is essentially an adaptive factor, against the protective power of heredity is the most striking feature of the law of Repetition. (See Galton's similar principle of Regression in Anthropology).

A careful study of our developing, degenerating, rudimental, and reversional organs amply demonstrates that man is now in a state of evolution hardly less rapid, I believe, than that which has produced the modern horse from his small five-toed ancestor. As far as I can see, the only reason why our evolution should be slower than that of the ancient horse is the frequent intermingling of races, which always tends to resolve types which have specialized, into more generalized types. Wherever the human species has been isolated for a long period of time, divergence of character is very marked, as will be seen in some of the races I refer to below.

To lighten the long catalogue of facts, gathered from many authors, I shall frequently allude to *habit*, but will ask you to consider it for the time as associational rather than causal. Pouchet says: "Man is a creature of the writing-table and could only have been invented in a country in which covering of the feet is universal;" he should have added the "eating-table." From the average man our fashions and occupations demand the play of the forearm and hand, the independent and complex movements of the thumb and finger; the outward turning

[1] Disadvantages of the Upright Position, article in American Naturalist, 1824, p. 1.

[2] The remarkable skulls and skeletons which have recently been discovered at Spy remove all doubts as to the normal, *i.e.*, racial character of the famous Néanderthal skull, which were entertained by Quatrefages and others. See Fraipont and Lohest, Archives de Biologie, 1887, p. 697.

[3] This is an epidermal or twitching muscle in the quadrupeds.

of the foot in walking. These are some of the most conspicuous features of modern habit.

The Skeletal Variations.[1]—In a most valuable essay by Arthur Thomson upon "The Influence of Posture on the Form of the Articular Surfaces of the Tibia and Astragalus in the Different Races of Man and the Higher Apes,"[2] we find clearly brought out the distinction between congenital variations and those which may be acquired by prolonged habits of life. It is perfectly clear from this investigation that certain racial characters, such as "platycnemism" or flattened tibia, which have been considered of great importance in anthropology, may prove to be merely individual modifications due to certain local and temporary customs. Thomson's conclusions are that the tibia is the most variable in length and form of any long bone in the body. Platycnemia is most frequent in tribes living by hunting and climbing in hilly countries, and is associated with the strong development of the tibialis posticus. The great convexity of the external condyloid surface of the tibia in savage races appears to be developed during life by the frequent or habitual knee flexure in squatting; it is less developed where the tibia has a backward curve and is independent of platycnemia. Another product of the squatting habit is a facet formed upon the neck of the astragalus by the tibia. This is very rare in Europeans; it is found in the gorilla and orang, but rarely in the chimpanzee We must therefore be on our guard to distinguish between congenital or hereditary skeletal characters which are fundamental, and "acquired" skeletal variations which may not be hereditary. The latter are of questionable value in tracing lines of descent, if not actually misleading; on the other hand, the teeth, as shown by Cope in his essay on "Lemurine reversion in human dentition," have distinct racial patterns and are reliable indices of consanguinity because their form cannot be modified during life.

The main features of present evolution in the backbone are the elaboration of the spines of the cervical vertebræ, the increase of the spinal curvatures, the shortening of the centra of the lumbar vertebræ and shifting of the pelvis upward, whereby a lumbar vertebra is added to the sacrum and subtracted from the dorso-lumbar series.

Cunningham[3] has found that the division of the neural spines in the upper cervical vertebræ distinguishes the higher races from the lower. The spine of the axis is always bifid, but the spines of the cervicals three, four, and five, are also, as a rule, bifid in the European, while they are single in the lower races. The same author shows[4] that the bodies of the lumbar vertebræ are altering, by widening and shortening, to form a firmer pillar of support, with a compensating increase in the length of the intervertebral cartilages. In the child the vertebræ present more nearly their primitive elongate compressed form. With this is associated an increase of the forward lumbar curvature (Turner);[5] the primitive (*i.e.*, Simian) curve was backward; even in the negroes the collective measurement of the posterior faces of the five lumbars is greater than the anterior, in the proportion of 106 to 100; whereas in the white the collective anterior faces exceed the posterior in nearly the same proportion—100 to 96.

The lower region of the back is also the seat of one of the most interesting and important of the changes in the body, namely, the correlated evolution of the inferior ribs, the lumbar vertebræ, and the pelvis—to which embryology, adult and comparative anatomy, and reversion all contribute their quota of proof. In most of the anthropoid apes, and therefore presumably in the pro-anthropos, there were thirteen complete ribs and four lumbar vertebræ, while man has twelve ribs and five lumbars. Thus we may consider the superior lumbar of adult man as a ribless dorsal; not so in the human embryo, however, for Rosenberg[1] has found a cartilaginous rudiment of the missing 13th rib upon the so-called first lumbar. Atavism contributes an earlier chapter in the history of this region, for Birmingham[2] reports, out of fifty cases examined in one year, two in which there were six lumbars, and in each the 13th rib was well developed; this is an interesting example of "correlated reversion," for as the pelvis shifted downward to its ancestral position upon the 26th vertebra, the 13th rib was also restored. The other ribs are in what the ancients styled a "state of flux;" our 8th rib has been so recently floated from the sternum that, and according to Cunningham,[3] it reverts as a true rib in twenty cases out of a hundred, showing a decided preference for the right side. Regarding also the occasional fusion of the 5th lumbar with the sacrum and the unstable condition of the 12th rib, which is, by variation rudimentary or absent, Rosenberg makes bold to predict that in the man of the future the pelvis will shift another step upward to the 24th vertebræ, and we shall then lose our 12th rib. The upright position, and consequent transfer of the weight of the abdominal viscera to the pelvis, may be considered the habit associated with this reduction of the chest; at all events, in the evolution of quadrupeds there is a constant relation of increase between the size of the posterior ribs and the weight of the viscera, until the rib-bearing vertebræ rise to twenty and the lumbars are reduced to three.[4] It would be interesting to note the condition of the ribs in some of the large-bellied tribes of Africans in reference to this point.

The coccyx has naturally been the centre of active search for the missing flexible caudals. As is well known, the adult coccyx contains but from three to five centres, while the embryo contains from five to six. Dr. Max Bartels has made "Die geschwänzten Menschen" the subject of an exhaustive memoir upon cases of the reversion of the tail, while Testut records all the primitive tail muscles in various stages of reversion. Watson reports that the curvatores coccygia (-depressores caudæ) only occur in 1 in 1,000 cases.

This suggests a moment's digression to consider the different phases of reversion. The 13th rib recurs by what Gegenbaur,[5] calls "neogenetic reversion," for it is simply the anomalous adult development of an embryonic rudiment. Under neogenetic reversions many authors also include cases of the "arrested development," or persistence of an embryonic condition to adult life, such as the disunited odontoid process of the axis vertebra, which happens to repeat a very remote ancestral condition. I think such cases may illustrate a reversional tendency, although many cases of arrested development, such as anencephaly, have no atavistic significance whatever.[6] More rare and far more difficult to explain are the "palæogenetic reversions," in which the anomaly, such as the supracondylar foramen, reverts to an atavus so remote that the rudiment is not even represented in the embryo.

The features of skull development are primarily the increase of the cranium and the late closure of the cranial sutures, in contrast with the more complete and earlier closure of the facial sutures.

So far as I can gather this seems to be another region where the white and colored races present reversed conditions; the early closure and arrest of brain development in the negroes is well known; the later closure among the whites is undoubtedly an adaptation to brain growth. In his valuable statistics upon the Cambridge students, Galton says: "Although it is pretty well ascertained that in the masses of population the

[6] Anencephaly, it should be said, is frequently associated with numerous reversions.

brain ceases to grow after the age of nineteen, or even earlier, it is by no means the case with university students. In high honor men head growth is precocious, their heads predominate over the average more at nineteen than at twenty five."

Many of the cases of arrested closure of facial sutures are reversional, as they correspond with the adult condition of other races, such as the divided malar, or os Japonicum. The human premaxillary, a discovery with which Goethe's name will always be associated, is sometimes partially, more rarely wholly, isolated; it is late to unite with the maxillary in the Australians, and has been reported entirely separate in a New Caledonian child (Deslongchamps) and in two Greenlanders (Carus). The orbito maxillary frontal suture, cited by Turner as a reversion to the pithecoid condition, is believed by Thomson,[1] after the examination of one thousand and thirty-seven skulls, to be merely an accidental variation, without any deeper significance. The development of the temporal bone from two centres, observed by Meckel, Gruber, and many others, is considered by Albrecht a reversion to the separate quadrate of the sauro-mammalia. This I think is in the highest degree improbable (see "Limits of Reversion"). The open cranial and closed facial sutures are apparently associated with our increasing brain action and decreasing jaw action; in one case the growth is prolonged and the sutures are left open, in the other, the growth is arrested and the sutures are closed.

Is the lower jaw developing or degenerating? This question has recently been the subject of a spirited controversy between Mr. W. Platt Ball,[2] representing the Weismann school, and Mr. F. Howard Collins,[3] supporting Herbert Spencer's view that a diminishing jaw is one of the features of our evolution which can only be explained by disuse. Mr. Collins finds that, relatively to the skull, the mass of the recent English jaw is one ninth less than that of the ancient British and, roughly speaking, half that of the Australian. He appears to establish the view that the jaw is diminishing.

Closely connected with this is the evolution of the teeth; how are they tending?

Flower[4] has shown, as regards the length of our molar series, that we, together with the ancient British and Egyptians, belong to a small-toothed or "microdont" race; the Chinese, Indians (North American), Malayans, and Negroes in part, are intermediate or "mesodont," while the Andamanese, Melanasians, Australians, and Tasmanians are "macrodont." While undersize marks the molars as a whole, the wisdom tooth is certainly in process of elimination; it has the symptoms of decline; it is very variable in size, form, and in the date of its appearance, is often misplaced, and is not uncommonly quite rudimentary (Tomes).[5] Here is another instance where the knife-and forkless races reverse our degeneracy, for in them not only is the last normal molar (m. 3) large and cut long before the traditional years of discretion, but in the first two lower molars are found two intermediate cusps (Tomes)[6] which are variable or absent in us (Abbott); moreover, in the macrodont races a surplus molar[7] (m. 4) is sometimes developed. Mummery reports nine such cases among three-hundred and twenty-eight West Africans (Ashantis). As an instance of associated habit I may here mention that Dr. Lumholtz, the Australian explorer, informs me that in adult natives the teeth are worn to the gum; in the absence of tools they are used in every occupation, from eviscerating a snake to cutting a root. A tour of inspection through any large collection of skulls brings out the contrast between the sound and hard-worn molars of the savage, and the decayed and little-worn molars of the white.

[7] This tooth has been found in several other macrodont tribes (Australians, Tasmanians, Neo-Caledonians), Fontan.

Upon the descent theory the reduction of teeth in the progenitor of man began as far back as the Eocene period, for not later than that remote age do we find the full complement of three incisors and four premolars in each jaw; now there are but two remaining of each. Baume, a high authority, believes he has discovered eleven cases of a rudimental reversion of one of these lost premolars[1] not cutting the jaw. Not infrequently both these missing teeth occur by reversion! It is difficult to conceive of reversion to such a remote period, yet it is supported by other evidence. An embryonic third incisor has, I believe, been discovered. As long ago as 1863, Sedgwick[2] recorded a case of six upper and lower incisors in both jaws, and appearing in both the milk and permanent dentitions; this anomaly was inherited from a grandparent, a striking instance of hereditary reversional tendency. We might consider that these cases of supernumerary teeth belonged in the same category as polydactylism, or additional fingers, which are not atavistic, but for the fact that they do not exceed the typical ancestral number, whereas the fingers do.

We owe to Windle[3] a careful review of the incisor reversions, in which he shows that the lost incisors reappear more frequently in the upper than the lower jaw (coinciding with the fact that the lower teeth were the first to disappear in the race); he considers that the lost tooth was the one originally next the canine, and concludes by adding our present upper outer incisor to the long list of degenerating organs.[4] He supports this statement by measurements and by citing cases in which it has been found absent. Yet the reduction of the jaws is apparently outstripping that of the teeth, if we can judge from the frequent practice among American dentists of relieving the crowded jaw by extraction.

We now turn to the arches and limbs. Flower has pointed out that the base of the scapula is widening in the higher races, so that the "index," or ratio of length to breadth, is quite distinctive. Gegenbaur associates this with the development of the scapulo-humeral muscles and the greater play of the humerus as a prehensile organ.

In general, the arm increases in interest as we descend toward the hand, both in the skeleton and musculature, because here we meet with the first glimpses of facts which enable us to form some estimate of the rate of human evolution. The well-known humeral torsion (connected with increased rotation) ascends from 152° in the polished stone age to 164° in the modern European. The intercondylar foramen, or perforation of the olecranon fossa, is exceptionally well recorded;[5] it is found in thirty per cent. of skeletons of the reindeer period; in the dolmen period it fell to twenty-four per cent.; in Parisian cemeteries between the fourth and tenth centuries it is found in 5.5 per cent.; it has now fallen to 3.5 per cent. The condylar foramen, occasionally forming a complete bridge of bone above the inner condyle and transmitting the median nerve and brachial artery, is known as the "entepicondylar" foramen in comparative anatomy, and is one of the most ancient characters of the mammalia; it reverts palæogenetically in one per cent. of recent skeletons, but much more frequently in inferior races (Lamb). In the wrist-bone is sometimes developed another extremely old structure—the os centrale. Gruber[6] reported its recurrence at .25 per cent. approximately. This is a case of neogenetic reversion, for Leboucq[7] shows that there is a distinct centrale in every human carpus in the first part of the second month, which normally fuses with the scaphoid by the middle of the third month.

The divergence of the female from the male pelvis is an important feature of our progressive development; it is proved by the fact that, as we descend among the lower races it becomes increasingly difficult to distinguish the female skeleton from the male, for the pelves of the two sexes are nearly uniform. Here it seems to me is a most interesting problem for investigation. Arbuthnot Lane's[1] views of the mechanical causes of this divergence, which are strongly Lamarckian, may be weighed with the theory of survival of the fittest, for a large female pelvis is perhaps the best example that can be adduced of a skeletal variation which would be preserved by natural selection, for reasons which are self-evident. The third trochanter of the femur is believed by Professor Dwight,[2] of the Harvard Medical School, to be a true reversion (one per cent.) in our race and not an acquired variation, as it is very frequently found among the Sioux (fifty per cent.), Laplanders, sixty-four per cent., and Swedes, thirty-seven per cent.; like the condylar foramen it is an ancient mammalian character.

The foot is full of interest in its association of degeneration and development with our present habits of walking; the great toe is increasing and the little toe diminishing, causing the oblique slope from within outward which is in wide contrast with the square toes in the infant or in the lower races. In many races the second toe is as long as the first, and the feet are carried parallel instead of the large toe turning out. If anyone will analyze his sensations in walking, even in his shoes, he will be conscious that the great toe is taking active part in progression, while the little toe is passive and insensitive. We are not surprised, therefore, to learn from Pfitzner[3] that we are losing a phalanx, that in many human skeletons (41.5 per cent. in women and thirty-one per cent. in men) the two end joints of the little toe are fused. The fusion occurs not only in adults, but between birth and the seventh year, and in embryos of between the fifth and seventh month. The author does not attribute this to the mechanical pressure of tight shoes because it is found in the poorer classes. He considers it the first act of a total degeneration of the fifth toe.

Variations in the Muscles.—The evolution of the muscles of the foot looks in the same direction.

As you know, the large toe in many of the apes is set at an angle to the foot and is used in climbing. It is still employed in a variety of occupations by different races. According to Tremlett,[4] the celebrated great toe of the Annamese, which normally projects at a wide angle from the foot, is contemptuously mentioned in Chinese annals of 2285 B.C., the race being then described as the "cross-toes." The long flexor of the hallux is apparently degenerating, showing a tendency to fuse with the flexor communis; the abductors and adductors of this toe are also degenerating, the latter being proportionately large in children (Ruge). The little toe exhibits only by reversion its primitive share of the flexor brevis (Gegenbaur); more frequently it varies in the direction of its future decline by losing its flexor brevis tendon entirely. Two atavistic muscles, the abductor metatarsi quinti[5] (always present in the apes), and the peroneus parvus (Bischoff), also point to the former mobility of the outer side of the foot. In general the bones of the foot are developing on the inner and degenerating on the outer side, with loss of the lateral movements of the hallux, and of all independent movements in the little toe. The associated habit is that the main axis of pressure and strain now connects the heel and great toe, leaving the outer side of the foot comparatively functionless.

The variations in the muscular system mark off more clearly the regions of contemporary evolution, and therefore are even more instructive than those in the skeleton. Muscular anomalies have, however, never been adequately analyzed. Even the remarkable memoir of M. Testut, "Sur les Anomalies musculaires," is defective in not clearly distinguishing between variations which look to the future, those which revert to the past, and those which are fortuitous, for the author is strongly inclined to refer all anomalies to reversion.

The law of muscular evolution is specialization by the successive separation of new independent contractile bands from the large fundamental muscles, while the law of skeletal evolution is reduction of primitive parts and the specialization of articular surfaces. The number of muscles in the primates as a whole has, therefore, been steadily increasing, while the number of bones has been diminishing. In man the number of muscles is probably increasing in the regions of the lower arm, and diminishing in every other region. The analysis is rendered very difficult by the fact that some muscles (*e.g.*, those connecting the shoulder with the neck and back) revert to a former condition of greater specialization when they were employed in swinging the body by the arms, and in quadrupedal locomotion; while other muscles (*e.g.*, those connecting the forearm and fingers) revert to a former simpler arrangement when the hand was mainly a grasping organ, and the thumb was not opposable.

As in the skeleton, we find that muscular anomalies include, 1, palæogenetic reversions, or complete restorations of lost muscles; 2, neogenetic reversions, or revivals of former types in the relations of existing muscles; 3, progressive variations, which either by degeneration or specialization point to future types; 4, fortuitous variations, which cannot be referred to either of the above.

Duval observes that the flexor longus pollicis repeats in reversion all the stages of its evolution between man and the apes, in which it is a division of the flexor profundus. Gruber and others have even observed the absence of the thumb tendon. This is true of all the new muscles. Of this Testut writes: "Ne dirait-on pas, en le voyant s'éloigner si souvent de son état normal, que la nature voudrait le ramener à sa disposition primitive, luttant ainsi sans cesse contre l'adaptation, et ne lui abandonnant qu' à regret l'une de ses plus belles conquêtes."

Speaking of the hand, Baker[1] says: "On comparing the human hand with that of the anthropoids, it may be seen that this efficiency is produced in two ways—first, increasing the mobility and variety of action of the thumb and fingers; second, reducing the muscles used mainly to assist prolonged grasp, they being no longer necessary to an organ for delicate work requiring constant readjustment." You have noticed the recent discovery that the grasping power of infants is so great that the reflex contraction of the fingers upon a slender cross bar sustains their weight; this power and the decided inward rotation of the sole of the foot and mobility of the toes are persistent adaptations. Our grasping muscle, the palmaris longus, is highly variable and often absent; like the plantaris of the calf, it has been replaced by other muscles, and its insertion has been withdrawn from the metapodium to the palmar fascia. In negroes we frequently find the palmaris reverting to its former function of flexing the fingers by insertion in the metacarpals.

The rise of muscular specialization by degeneration is beautifully shown in the extensor indicis, which, while normally supplying the index only, reverts by sending its former slips to the thumb, middle, and even to the ring finger. Testut[2] believes that the extension power of the middle and ring fingers has declined, as the cases of reversion point to greater mobility; the extensor minimi digiti is distinct and highly variable (Wood), often sending a slip to the ring finger.

The entire flexor group of the hand, excepting the palmaris, is apparently specializing. The demonstration by Windle[3] and Bland Sutton, that the origin of the flexors and extensors is shifting downward from their

original position, is evidence of an adaptation to the short special contractions required of them.

The abductor pollicis [1] is also progressive and variable (Wood); the reduplication of its inferior tendon, which is sometimes provided with a distinct muscle, apparently points to the birth of a second abductor. The opponens of the thumb is well established and constant. Variability seems to characterize both the developing and degenerating muscles; the latter are apt to be absent; it is rare that an important muscle, such as the extensor indicis, is absent, but such cases are reported.

It is interesting to note that the lost muscles of the body are almost exclusively in the trunk or shoulder, and pelvic arches, and not in the limbs. It will be remembered that the human shoulder-joint is exceptionally rigid, whereas in the quadrupedal state it was a factor in progression. Some of the muscular reversions in this quadrupedal region are the levator claviculæ (1 to 60, Macalister), trachelo-clavicularis, scalenus intermedius, acromio-basilaris (Champneys), transversus nuchæ (Gegenbaur). Apparently associated with the former swinging of the body by the fore limb in the arboreal life are the atavistic coraco-brachialis-brevis (Testut), the epitrochleo-dorsalis (Testut), and pectoralis tertius (Testut).[2]

Centres of Variability.—As the literature is so readily accessible I will not multiply illustrations of the innumerable congenital variations related to human evolution. I call attention to several important inductions. First, there are several centres in which both the skeletal and muscular systems are highly variable. Second, that the most conspicuous variations, and therefore the most frequently recorded, are reversions. Third, that structure lags far behind function in evolution.

The conclusions of Wood and Testut [3] are that variability is independent of age or sex, of general muscularity, and of abnormal mental development. Wood found 981 anomalies in 102 subjects; of these, 623 were developed upon both sides of the body, while 358 were unilateral. Of still greater interest are the statistics collected by Wood between 1867–68 in the dissecting-room of King's College, upon 36 subjects (18 of each sex). These show that there are more anomalies in the limbs than in the trunk; that anomalies are rare in the pelvis; that there were 292 anomalies in the anterior limbs to 119 in the posterior; that in both limbs the anomalies increase toward the distal segments, culminating in the muscles of the thumb, where they rise to ninety per cent. (mainly flex. long. pollicis, and abd. long. pollicis). These facts seem to prove conclusively that while variation is universal it rises to a maximum in the centres where human evolution is most rapid; here are Herbert Spencer's conditions of unstable equilibrium. This has a direct bearing, as I shall show, upon our theory of heredity.

Fortuitous Congenital Variations.—I have thus far considered only those variations which apparently have a definite relation to the course of human evolution. There is an entirely different class of congenital variations which may be described as fortuitous or indefinite because they do not occur in any fixed percentage of cases; they are liable to take any direction; they cannot be considered reversional because they are not found in the hypothetical atavus, and there is not sufficient evidence to cause us to consider them as incipient features of our future structure.

Some may not be truly congenital (*i.e.*, springing direct from the germ-cells) but may be merely deviations from the normal course of development. I may instance the variations in the carpus recorded by Turner [4] in which the trapezium and scaphoid unite, or the trapezoid and semilunar divide, or the astragalus and navicular unite (Anderson).

The best examples of fortuitous congenital variations are seen in supernumerary fingers and vertebræ. The eighth cervical vertebra, bearing a rudimentary rib,[1] is not a reversion because the most remote ancestors of man have but seven cervicals. In cases where a rib is developed upon the seventh cervical, however, the reversion theory is perhaps applicable because rib bearing cervicals are relatively less remote. The same distinction applies to polydactylism. How absurd it is to consider a sixth finger atavistic, when we remember that even our Permian ancestors had but five fingers.

We cannot, however, class as purely fortuitous a variation which occurs in a definite percentage of cases presenting twenty-four different varieties, but occurring in the same region. Such is the much-discussed [2] musculus sternalis, a muscle extending vertically over the origin of the pectoralis from the region of the sterno-mastoid to that of the obliquus externus. Testut lightly applies his universal reversion theory, and as this muscle is not found in any mammal considers it a regression to the reptilian presternal (Ophidia)! Turner also considered it as reversional in connection with the panniculus carnosus, the old twitching muscle of the skin, which plays so many freaks of reversion in the scalp and neck; this view is negatived by the fact that this muscle is innervated by the anterior thoracic (Cunningham, Shepherd) which would connect it with the pectoral system, or by the intercostal nerves (Bardeleben). Although the high percentage of recurrence in the sternalis in anencephalous monsters (ninety per cent. according to Shepherd) supports the reversion view, it is offset by the high percentage (four per cent.) in normal subjects, for this is far too high for a structure of such age as the reptilian presternal. Cunningham has advanced another hypothesis, first suggested by the frequency of this anomaly in women, that this is a new inspiratory muscle, having its origin in reversion, but serving a useful purpose when it recurs, and therefore likely to be perpetuated.

These fortuitous variations, as well as variations in the proportions of organs, play an important part in the present discussion upon heredity, for it is believed by the Weismann school that such variations, if they chance to be useful, will be accumulated by selection and thus become race characters.

The Limits of Reversion.—There is such a wide difference of opinion upon the subject of reversions that it is important to determine what are some of the tests of genuine reversions? How shall we distinguish them from indefinite variations or from anomalies like the sternalis muscle, which strain the reversion theory to the breaking-point?

Testut,[3] Duval, and Blanchard take the extreme position that almost all anomalies reproduce earlier normal structures, and that the exceptions may be attributed to the incompleteness of our knowledge of comparative anatomy. I may here observe that popular as the descent theory has recently become in France, neither these anthropologists nor the palæontologists show a very clear conception of the phyletic or branching element in evolution. If they do not find a muscle in the primates they look for it in other orders of mammals. Now, since these other branches diverged from that which gave rise to man at a most remote period, the discovery of a similar muscle may be merely a coincidence; it is by no means a proof of reversion.

The first test of reversion is therefore the anatomy of the atavus, and this is derived partly from the palæontological record of the primates, partly from the law of divergence, viz., that features which are common to all the living primates were probably also found in the stem form which gave rise to man; finally, from the comparative anatomy of the living anthropoidea.

The second test is whether a structure passes the limits of reversion as determined by cases of atavism in which there can be no reasonable doubt. Two of these phe-

nomena have recently been discussed, which seem to extend the possibilities of reversion back to structures which were lost at a very remote period. I refer to papers by Williams and Howes. Williams [1] has analyzed 166 recorded cases of polymastism; he finds that supernumerary nipples of some form occur in two per cent., and that in all except four of the cases examined the anomalies, tested by position, etc., support the reversion hypothesis. In the living lemurs, which form a persistent primitive group of monkeys, we find that the transition from polymastism to bimastism is now in progress by the degeneration of the abdominal and inguinal nipples, it is fair to assume that the higher monkeys also lost their abdominal nipples at a primitive stage of development, and therefore that cases of multiple nipples indicate reversion to a lower Eocene condition! Howes [2] has recently completed a most interesting study of the "intranarial epiglottis," or cases in which the epiglottis is carried up into the posterior nares, as in young marsupials and some cetacea, to subserve direct narial respiration. This has now been observed to occur by reversion in all orders of mammals, including the monkeys and lemurs. One case has also been reported by Sutton of its occurrence in a human fœtus. This is apparently a human reversion to a structure much older than the age of the lemurs.

many cases, both of reversions (as in the teeth) and indefinite variations being hereditary, that is, reappearing in several generations, or skipping a generation and recurring in the second.

Summary.—There are clearly marked out several regions in the human body in which evolution is relatively most rapid, such as the lower portion of the chest, the upper cervicals, the shoulder girdle in its relation to the trunk, the lower portion of the arm and hand, the outer portion of the foot. We notice that these regions especially are centres of adaptation to new habits of life in which new organs and new relations of parts are being acquired, and old organs abandoned.

We observe, also, that all parts of the body are not equally variable, but these centres of evolution are also the chief centres of variability. The variations here are not exclusively, but mainly, of one kind; they rise from the constant struggle between adaptation and the force of heredity. Here is a muscle like the extensor indicis attempting to give up an old function and establish a new one; it maintains its new function for several generations, and then goes back without any warning to a function which it had thousands of years ago. Thus the force of reversion strikes us as a universal factor.

Now the singular fact about reversion is the frequent

* It is probable that some of these muscles are represented in the fœtus.

The third test is the inverse ratio to time. It would seem, *a priori*, that the percentage of recurrence of atavistic structures should decrease as the extent of time elapsing since the structure disappeared increases. This law is apparently established in the case of the condylar and intercondylar foramina, and if we examine all the percentages which have been established, we see at once that they bear a ratio to time; compare the relative frequency of the ischio-pubic (fifty per cent.), dorso-epitrochlearis (five per cent.), and levator-claviculæ (1.66 per cent.) muscles with the periods which have elapsed since their past service. This is why it is so important to establish percentages for all our atavistic organs; fuller statistics will not only bear upon heredity, but I can conceive of their application to the extremely difficult problem of estimating geological time. We must, of course, establish as a standard cases of congenital variation in which the frequency of recurrence has been steadily declining in the same race between two known periods of time—an available structure is the intercondylar foramen or supratrochlear foramen, as recorded by Blanchard, Shepherd, and others.

The reversional tendency is hereditary. There are

[1] Journal of Anatomy and Physiology, 1891, p. 224.
[2] Ibid., 1889, p. 587.

proof it affords of what Galton has called "particulate inheritance." When the extensor indicis reverts, all the muscles around it may be normal; therefore we are obliged to consider each of these muscles as a structure by itself, with its own particular history and its own tendencies to develop or degenerate. Thus it is misleading to base our theory of evolution and heredity solely upon entire organs; in the hand and foot we have numerous cases of muscles in close contiguity, one steadily developing, the other steadily degenerating. Reversion very rarely acts upon many structures at once; when it does, we have a case of diffused anomaly, some repetition in the epidermis, or in the entire organism of a lower type.

Yet in spite of reversion and the strong force of repetition in inheritance, the human race is steadily evolving into a new type. We must, it seems to me, admit that an active principle is constantly operating upon these particular structures, guiding them into new lines of adaptation, acting upon widely separate minor parts, or causing two parts, side by side, to evolve in opposite directions, one toward degeneration, the other toward development.

I may now recall the two opposed theories as to what this active principle is:

The first, and oldest, is that individual adaptation, or

the tendencies established by use and disuse upon particular structures in the parent are, in some degree, transmitted to the offspring, and thus guide the main course of variation and adaptation.

The second is that all parts of the body are variable, and that wherever variations take a direction favorable (that is adaptive) to the survival of the parent they tend to be preserved; where they take the opposite direction they tend to be eliminated. Thus in the long run, adaptive variations are accumulated and a new type is evolved.

It is evident at once, from a glance over the facts brought forward in this lecture, that the first theory is the simplest explanation of these facts; that use and disuse characterizes all the centres of evolution; that changes of structure are slowly following our changes of function or habit.

But while the first explanation is the simplest, it by no means follows that it is the true one. In fact, it lands us in many difficulties, so that I shall reserve the *pros* and *cons* for my second lecture upon Heredity. The Lamarckian theory is a suspiciously simple explanation of such complex processes.

(To be continued.)

GOTTSTEIN'S NEW IMPROVED CURETTE FOR THE REMOVAL OF ADENOID VEGETATION FROM THE VAULT OF THE PHARYNX.[1]

By FRANK E. MILLER, M.D.,

THROAT SURGEON TO THE VANDERBILT CLINIC; CONSULTING THROAT SURGEON TO ST. JOSEPH'S HOSPITAL, NEW YORK.

In October, 1890, I was presented with one of Gottstein's newly improved curettes, by Dr. G. M. Edebohls, of this city, on his return from the Berlin Medical Congress. He remarked at the time that it was the latest instrument used for the removal of adenoid vegetation from the vault of the pharynx, and, so far as I am aware, it was the first used in this country.

The success with which I have met since then in its use, coupled with the belief that it will create a revolution in operations for adenoid growths, has induced me to present a brief description of the instrument, and its *modus operanai*.

It is a source of great satisfaction when the operator can take the smallest child, suffering from enlargement of the pharyngeal tonsil or adenoid growth, and without danger, or the use of an anæsthetic, remove in one sitting the entire growth. To appreciate the advantages this instrument possesses in the removal of adenoid vege-

FIG. 1.

FIG. 2.

tation, a knowledge of the anatomy of the parts involved as well as of the various instruments is necessary.

The naso-pharyngeal space is formed above by the body of the sphenoid bone and the basilar portion of the occipital. The posterior wall, almost a continuation of the upper, is formed by the anterior surface of the atlas and the first cervical vertebræ. The anterior wall is bounded by the horizontal portion of the palate, the winged process of the sphenoid, and the posterior surface of the soft palate, which by its contraction forms the lower boundary of this space. The lateral walls are formed by the fossæ of Rosenmuller, the tubal prominences, and the opening of the Eustachian tubes. If we make a vertical section through the skull, *i.e.*, from above downward, we find that the posterior nasal cavity or naso-pharyngeal cavity, forms a space as depicted in Fig. 1.

Should we make such a section as to cut through the Eustachian orifices, we should find that our post-nasal cavity would resemble Fig. 2, the tubal prominences indicating the most narrow portion of the cavity.

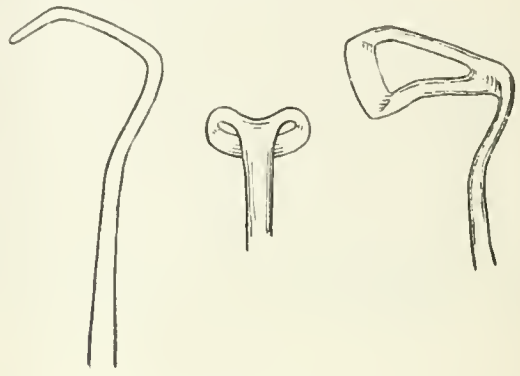

FIG. 3.

As we view our schematic outlines, we perceive there are three great points to be avoided in adenotomy: 1st, the soft palate; 2d, the turbinated bodies; 3d, tubal prominences. As we shall note later, the peculiar curve of this instrument (see Fig. 3) prevents any possibility of injury to these structures, which cannot be said of other instruments now used for the removal of these growths. The mucous membrane of the naso-pharyngeal space is of importance, as on the upper posterior and lateral walls it is rich in cellular structure and abounds in follicles. This follicular mass bears the name of adenoid tissue, pharyngeal tonsil, or Luschka's tonsil; when this becomes enlarged or hypertrophied we have the condition known as adenoid vegetation, or enlargement of pharyngeal tonsil.

Nearly every practitioner of medicine has patients presenting the symptoms characteristic of this disease. They are, briefly stated:

1. Change in voice, loss of resonance, the words sounding dull and muffled; this change of voice is also noticeable in acute angina and hypertrophy of the tonsils.

2. Inability to breathe through the nose, thereby compelling the child to breathe through the mouth. The child sleeps with its mouth open and snores loudly. As a result we have drooping of the lower lip, and the face assumes that heavy, stupid expression so pathognomonic of this condition. The sense of hearing is also affected. According to Hartman and W. Mayer, in about fourteen per cent. of cases there are disturbances of hearing, that may be of slight nature such as ringing in the ears, or there may be deafness present in a high degree. The senses of taste and smell also suffer. The child may complain of pain in the occipital, or a sensation of pressure in the frontal, region. If the condition be allowed to progress the child becomes anæmic, and the chest remains flat, undeveloped, and sunken in. This condition is often overlooked by the family physician; or, when spoken to by the parents concerning the mouth breathing of the child, he attributes it to "a bad habit, which must be corrected."

The frequency of these growths can be readily appreciated when one reviews the statistics of Dr. F. Chappel, of New York, who found, by personal examination, that sixty out of one thousand school children in this city had adenoid growths at the vault of the pharynx. In 9,000 cases treated in the class of Professor G. M. Lefferts, at the Vanderbilt Clinic, 593 were cases with adenoid vegetations. (In 1,000 cases, 61 were adenoids.) It is a

[1] Read before the Hospital Graduates' Club of New York City.

matter, therefore, of no little importance that this condition be early recognized, not alone by the specialist, but by the general practitioner as well, for with him rests the power of relieving, perhaps, many children of the disagreeable symptoms connected with this condition, and of preventing much future suffering, mental infirmity, as well as facial and physical deformity.

Removal of these growths is generally effected by surgical interference. When the vegetations are not large we can use the cautery, but the larger growths are best extirpated by forceps, snare, or curette. Guye, of Amsterdam, used his finger-nail to scrape away the growth. Copart and Lenox Browne used a curette connected to the finger by means of a double cylinder, which also acts as a finger-shield. Chiari, of Vienna, uses a cold snare introduced through the anterior nares. This method is effective and has the advantage of causing but little bleeding, but it requires a skilful hand. Probably in the majority of operations the post nasal cutting forceps are used. They consist of a pair of curved forceps with sharp cup-shaped blades at their end. These require to be introduced several times before the growths are completely removed. To remove them all in one sitting with this instrument requires the use of an anæsthetic. Anyone who has witnessed an operation of this kind under an anæsthetic, and has beheld the struggling of the patient as the blood trickles down the throat, the oft-repeated vomiting of blood during the operation, and the almost asphyxiated condition of the patient, can well wish for some new instrument whereby these dangers can be avoided. Moreover, there is the possibility of injuring one or other of the turbinated bodies, Eustachian tubes, or soft palate. With Gottstein's newly improved curette this possibility is avoided. No anæsthetic is required, and one sitting usually suffices to remove the growths entire. By reference to Fig. 3 the shape of Gottstein's improved curette can be seen.

The old curette consists of a shank with a slight curve at one end, to which is attached at right angles a hollow, triangular curette of steel, having at its base a bevelled edge sharpened toward the apex. The improvement consists in the peculiar curvature of the cutting part of the instrument. This curvature is specially adapted to the anatomy of the pharynx, so that there is no danger of injuring or removing any part of the pharynx other than the hypertrophied pharyngeal tonsil.

The instrument is introduced sideways (see Fig. 4)

Fig. 4.

Fig. 5.

into the patient's mouth, passed beneath the soft palate and up along the anterior wall of the naso-pharyngeal space, with the cutting edge directed toward the posterior wall, until the vault of the pharynx is reached. The physician then places his left hand behind the patient's head in order to hold it securely, depresses the handle of the instrument so that the cutting edge is brought directly in front (see Figs. 5 and 6) of the adenoid growth, and with a backward and downward movement removes the growth. It is always well to have an assistant hold the patient's hands. The advantages are: 1. Quickness. 2. No necessity for ether. 3. Thoroughness, provided the instrument be properly introduced. Besides, the shape of the instrument is such that no damage to any of the adjacent structures is possible, as in the case of post-nasal forceps; and also, no cicatrization follows, as is the case when the galvano-cautery is used. The operation is simple, requiring but little skill, and the technique can be easily acquired by every physician.

I base the above conclusions upon seventy-eight adenotomies, which have been attended with uniform suc-

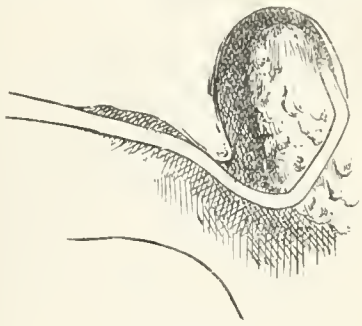

Fig. 6.

cess. Several of my *confrères* at the clinic, Drs. Richards, Colles, and McEvoy, have found it equally effective. To the last-named I am under obligations for assistance and material.

TREATMENT OF ŒSOPHAGEAL STRICTURE BY PERMANENT TUBAGE.

By WALTER F. CHAPPELL, M.D., M.R.C.S. Eng.

NEW YORK.

Stricture of the œsophagus, however produced, causes so much distress that any suggestions for its relief, or to benefit the condition of the sufferer, must be acceptable to every practitioner. In every case of organic stricture we have to decide on the best manner of nourishing and sustaining the patient in the later stages of the disease.

Gastrotomy has been most relied upon to effect this end, but owing to the seriousness of the operation, and the usual weakened condition of the patient when it is performed, the result obtained cannot be considered a success; in fact, the operation itself often proves fatal, and is therefore only resorted to that the patient may escape the horrors of starvation. The use of a short tube for feeding was advocated by Sir Morell Mackenzie many years ago. In 1884 Dr. Charters Symonds exhibited a short tube before the Clinical Society of London, very similar in design and for the same purpose as that recommended by Mackenzie. This tube was an improvement in shape and manufacture on Mackenzie's, and was intended for permanent retention, while Mackenzie only allowed his to remain in position a few days at the most.

The possibility of keeping the tube in the œsophagus for from one to six months, as has been reported by several observers, greatly increases its usefulness, until at the present time most cases of malignant stricture, if seen moderately early, can be so managed as to render gastrotomy unnecessary; indeed, in very advanced cases we can frequently introduce a small tube and sustain the patient until the disease has progressed to a further degree and implicated some other organ which terminates life and spares the patient a gastrotomy or the trials of slow starvation.

When the disease ulcerates through into the trachea the short tube cannot be retained in the œsophagus. As this condition occurs only very late in the case, the œsophageal opening rarely closes completely if a short tube has been used, and the patient can be nourished with a long feeding-tube for the time which he needs it. The use of the short tube has been confined chiefly to cases of malignant stricture, and has therefore been only palliative in its usefulness, but I have found it of great service as a curative agent in other forms of stricture. In recent and slight cases of traumatic stenosis of the gullet, where we may expect a good result from gradual

dilatation, the presence of a short, silk, gum-elastic tube at the seat of stricture, in the interval between the passing of the bougies, will hasten the restoration of the calibre of the œsophagus. When used for this purpose we need a set of tubes each a little smaller in diameter than the corresponding bougie to be employed. After passing the bougie into the œsophagus and allowing it to remain ten or fifteen minutes, it is removed, and a suitable short tube introduced and kept in position four or five days, until the next-sized bougie is passed. This method of dilatation prevents contraction of the stricture in the interval between the passing of the bougies. We also get the dilating effect of the mere presence of the tube in the stricture. In some cases of nervous or hysterical strictures it is also of service when they have resisted the continuous passing of the bougie for some time, or have recurred. In one case I employed a soft rubber tube, and allowed it to remain in position two weeks. After its removal the patient swallowed perfectly for a month, when the attack recurred. The tube was reintroduced and allowed to remain a week, when recovery was complete and remained so. The moral effect of the presence of the tube was no doubt the chief element in recovery.

It seems to me that a similar use of the tube might be made after internal œsophagotomy. After this operation we rely upon the passing of bougies to maintain the calibre of the tube, and while I have not had an opportunity of testing it, it seems from our experience with short tubes in gradual dilatation that we have every reason to expect that an introduction of a silk gum-elastic tube, say four or five days after an internal œsophagotomy, and used in conjunction with the bougies, would be a great assistance to us in restoring the œsophagus to a more normal condition. Of course, better success may be expected when only a short part of the œsophagus is implicated in the stricture.

A description of the tubes used and the methods of introduction, with some suggestions as to the management of the cases, will, I think, be valuable. The tubes are made of gum elastic on silk web, or of soft rubber with thickened walls. The former are the most useful, as in fact it is only in a few cases that the soft rubber could be used. The length of the tube varies from four to seven inches, according to the length of the stricture, or if there are two strictures close together the tube may be long enough to include both. The soft-rubber tube rarely requires to be more than four inches long, as it is only applicable to strictures at the upper extremity of the œsophagus and can be easily introduced and so nicely adjusted in position that a tube of this length is usually sufficient. The superior extremity is funnel-shaped and rests on the top of the stricture. The small end is rounded and has an eye about half an inch from the extremity. The bone of the tube is as large as possible consistent with the strength of the tube, and extends past the eye to the inferior extremity. This allows the whalebone introduced to be carried to the bottom and then easily removed. According to my experience, however, it is just as well, if not better, to have the small end of the tube open, as it is not so likely to get filled with food. A stout silk thread of requisite length is then passed through the tube on either side of the funnel-shaped extremity. The tube is then washed in a carbolic solution and the outside coated with vaseline. The position and size of the stricture have of course been ascertained by bougies

The œsophagus is disinfected as much as possible, by directing the patient to swallow a solution for that purpose; I then give two or three teaspoonfuls of a one per cent. solution of olive-oil and cocaine. This not only facilitates the passing of the tube by its lubricating properties, but also shrinks the tissues and increases the calibre of the stricture to a small degree.

When the stricture is at the upper extremity of the œsophagus the tube can be introduced by simply engaging a bougie in its funnel end; but when it is further down we have to guard against the tube coiling up during introduction. For this purpose Dr. Symonds recommends a whalebone introducer, which is passed to the bottom of the tube, and outside of this a gum-elastic sheath, which is engaged in the funnel extremity. The whalebone will keep the tube stiff, and pressure may be made on the sheath from the top of the tube. Plenty of time must be taken, and only the gentlest manipulations employed. If the stricture is not too narrow you can get some assistance by directing the patient to swallow while you exert gentle pressure. The silk thread which is fastened to the tube keeps it under control, and is usually brought out of the mouth and fastened on the cheek. I have found this a very troublesome procedure, as a good deal of mucus always accumulates in the pharynx and mouth, and the presence of a thread in the mouth increases this to such a degree that it is almost unbearable to some patients. To obviate this I passed a very small soft rubber catheter through the nose into the mouth and secured the thread to it, then drew it up through the nose, removed the catheter, and left the thread in one of the nasal passages. The thread was then fastened to the cheek with plaster. By this means the thread is kept in the back of the pharynx and well out of the way of the fauces. In the two cases in which I employed this method the patients said they had very little discomfort.

The soft-rubber tube is prepared for introduction in the same way as the silk-elastic, and when the case is suitable for its employment can be easily introduced with the finger and a bougie. If the case is progressing favorably under the tubage treatment it is advisable to remove the tube once in two weeks, and after cleansing reintroduce it. In cases of malignant stricture it is necessary at first to remove the tube more frequently than this, owing to the dilatation which often follows the first introduction.

The following are short histories of a few cases treated with the tubes:

Mrs. V——, aged fifty-one, came under my care on June 2, 1890. She had an excellent family history. Sixteen years before the present illness began she had some difficulty in swallowing solids. The physician attending her at that time diagnosed it as nervous stricture of the œsophagus. He blistered her back and throat and gave her tonics. She did not lose flesh or strength, and after about eighteen months was so much improved that she discontinued the treatment. Since that time, however, and up to the beginning of the present illness, she was obliged to swallow solids with care, as she found they would stick in her throat, and if she drank quickly she choked. Soon after Christmas, 1889, she found the slight difficulty in swallowing was increasing, and two weeks later it was very pronounced. From this time she rapidly grew worse, and by April 1st was reduced to fluid diet. Her voice began to grow hoarse about this time. These symptoms progressed until June 2d, when she came under my observation. I found her much emaciated, pale and haggard in appearance, and she had swallowed nothing for thirty six hours. Not having a suitable long tube at hand, I tried to pass a No. 7 English gum-elastic catheter, but was not successful. A hypodermic of morphine was then administered and the patient directed to swallow one-half a grain of cocaine dissolved in water. In twenty minutes I passed the catheter without difficulty and gave some milk. A few hours later a tube was introduced and food again given. The following day I passed a No. 6 bougie and found the stricture was sixteen inches from the upper incisor teeth, which is the usual point from which measurement is made.

From the history, appearance of the patient, and great salivation present, there could be no doubt a malignant growth had to be dealt with.

On June 6th I improvised a short tube by taking sufficient of the upper extremity of a long feeding-tube, which has a funnel shaped end, and introduced it at the seat of stricture. The first day it caused some coughing, but after that she swallowed without difficulty, providing she

did so slowly. A week later I removed the tube and put in a new one which I had had made. This she wore continuously until July 14th, when she began to feel nauseated, and I was obliged to remove the tube. From June 10th till July 14th she gained seven pounds in weight and was much stronger and very comfortable. After the removal of the tube she swallowed liquids, but the vomiting and coughing was so great that she did not retain anything, and a thin, dark-brown, grumous fluid began to appear in the vomit; on the 17th she had a violent chill, followed by fever, the temperature going up to 103° F.; she was delirious and became comatose, and died the following day.

On post-mortem examination a malignant growth was found in the lower part of the œsophagus. It implicated about four inches of the œsophagus and had nearly destroyed its walls to that extent. It had also extended to the trachea and perforated it just above the right bronchus. The neighboring lung-tissue on both sides was implicated, and also the wall of the aorta. A carcinomatous mass about the size of a large hen's egg was found in the walls of the stomach, near the œsophageal opening. It protruded into the cavity of the stomach and was very vascular. Its surface showed signs of erosion and recent hemorrhage. The heart-walls were thin and pale, and the pericardium contained two ounces of pus.

Miss C——, aged twenty-seven; never had any special illness, but was always nervous. Had been in a house during the summer which was undergoing repairs and thought she caught malaria. While eating supper, about two weeks before consulting me, found she was suddenly unable to swallow anything solid; taking liquids also made her choke. When I saw her she was thin, pale, and weak, extremely nervous about her condition, as she was sure she felt a lump rise in her throat and choke her every time she attempted to swallow. After spraying the fauces with cocaine I passed a No. 10 œsophageal bougie with little effort, and the following day a No. 13, which was about full size for her. Mixed bromides and quinine were prescribed, and the patient told she could now swallow any food she wished. She returned in a week and reported that for a few days after her visit she was all right, but she now felt the lump in her throat and could not swallow. I again passed a full-sized bougie and sent her home only to have her return ten days later with another attack. These recurrences were repeated several times until she became quite despondent. I then introduced a soft-rubber short tube, about No. 10 in size, and let it remain for two weeks. During this time she took plenty of fluids and called to tell me that she was quite sure she could now take solids. A few days later I removed the tube and she was able to swallow perfectly for a month, when after some excitement the old trouble returned. The tube was again resorted to, and after four days she was quite well and remained so.

I have no doubt that in this case the tube hung free in the œsophagus soon after its introduction, and that the patient swallowed outside of it as well as through it. I have employed the tube in two other cases, one of hysterical stricture, where it was only a partial success, owing to nausea; the other, a mild traumatic stricture, where it was used as an aid to gradual dilatation with marked success. Not having any notes of these two cases I am unable to present them in detail.

It seems remarkable in case No. 1 which I have reported that so large a growth should be found in the stomach without causing any distress or symptoms which would draw attention to its presence. I only discovered it two or three days before death when the vomiting came on. Up to that time there had not been the slightest complaint of distress in the stomach.

Dr. S J. Mixter, of Boston, has suggested a new instrument for introducing the short tube. I have not used it, but Dr. Robert F. Weir, who has had considerable experience with it, tells me that he prefers it to any other.

22 East Forty-second Street.

A CASE OF SACRAL HYSTERECTOMY.[1]

By FRED. KAMMERER, M.D.,

SURGEON TO THE GERMAN AND ST. FRANCIS' HOSPITALS, NEW YORK.

Within the past ten years important progress has been made in the matter of attaining access to the organs of the pelvis, with a view to surgical manipulations upon them or their entire removal from the body. Such attempts were not new at the time, as a review of the history of vaginal hysterectomy and of the operations upon the rectum will teach us. But it was not until we had acquired a high degree of surgical self-assurance by the practice of antiseptic and aseptic methods that operations seeking to effect an entrance into the pelvis from its outlet found favor among the profession. Since then the latter have rapidly advanced to the position of universally recognized and even typical operative procedures. To the last of these surgical ventures, the operative interference with the female sexual organs after resection of the sacrum, a favorable reception has not been so generally accorded. Yet I believe that for the relief of certain conditions this method is better adapted than either laparotomy or vaginal hysterectomy. In this conviction I have ventured to place before the Society the following observation:

C. C——, married, thirty-five years of age, has had six children, and one miscarriage in January of last year. From this time on she has suffered from continual hemorrhages until March, when the cervix was amputated by one of our local gynecologists, apparently for incipient cancer. Her hemorrhages then ceased until two weeks before admission to the hospital (beginning of September). She has lately suffered much from an offensive discharge. On admission her general condition was certainly not encouraging. She was much emaciated and very anæmic. The vaginal portion and the collum had disappeared; the fornix of the vagina was continuous with an opening into the body of the uterus, which was surrounded by nodular ulcerated masses. The body of the uterus was not movable. In the right broad ligament no infiltration could be made out. The left broad ligament was much contracted, drawing the uterus to the left. Close to the uterus it was converted into a mass of infiltrated tissue, continuous with the body of the uterus, but not reaching quite to the wall of the pelvis. Having decided on sacral hysterectomy the patient was put under ether and placed on her right side, with her lower limbs moderately flexed, the left thigh being brought somewhat nearer the abdominal walls. An incision about six inches long was carried from the posterior border of the anus, over the coccyx and sacrum, in the median line down to the bone. The soft parts covering the posterior surface of the sacrum were detached to either side until the lateral borders of the bone were reached. After division of the sacral ligaments I removed that part of the sacrum and coccyx lying below the third sacral foramina with a bone forceps, cutting the bone transversely. The rectum was drawn to the right, and with the left index in the bowel as a guide, its attachments on the left side were separated with the knife, exposing the upper part of the vagina and the cul-de sac without the least difficulty. The peritoneum was readily recognized by its bulging, when pressure was exerted on the abdomen. It was caught with forceps and incised. The tumor, comprising the uterus and left ligament, immediately presented, but unfortunately I also very soon discovered a complication for which I was not prepared. The tumor had perforated into the peritoneal cavity, and had formed a broad attachment with the sigmoid flexure. Moreover, the left ureter was seen emerging from the carcinomatous mass. It was ligated and cut. Resection of the involved intestine was considered out of question on account of the patient's condition. The bowel was accordingly peeled off from the uterus, fortunately without tearing into its lumen, and then the removal of the carcinomatous mass became an

[1] Read before the New York Academy of Medicine, Section on Surgery, December 14, 1891.

easy matter. The large vessels were tied as they were cut during the division of the broad ligaments. With an incision in the vagina the tumor was readily detached from the bladder and rectum by cutting through the healthy tissue of the vaginal wall. In consideration of the divided ureter and the cancerous infiltration of the gut, I did not close the peritoneal cavity, but tamponed it with iodoform gauze. The patient rallied well from the operation, which had lasted two hours. On the second day two and a half ounces of urine were secreted; the first day's amount was equally small, but it had not been accurately measured. On the third it increased to twenty ounces, and then decreased again, corresponding to the continual flow of urine from the cut ureter into the wound, which began on the same day On the fourth day symptoms of iodoform intoxication set in, and sterilized gauze was substituted for iodoform gauze. but the patient died on the seventh day. At the post-mortem examination a strip of iodoform gauze was found among the intestines, which had escaped detection at the dressing. There was no peritonitis, and the cavity of the wound was lined with healthy granulations.

In determining the position into which the patient was placed during operation, I was guided by the infiltration of the left broad ligament, and the consequent lateroflexion of the uterus to the left. If the right broad ligament had been invaded, I should have placed the patient on her left side. In this way the rectum will be most readily held aside, assisting in this by its own weight. I have operated for cancer of the rectum several times in the knee-elbow posture, and I have been well pleased with it when the seat of disease was at some distance from the anus. The manipulations for detaching the rectum and sigmoid flexure from the sacrum are more easily conducted when the patient is thus placed, but in extirpation of the uterus I should adhere to the lateral position, varying it according to circumstances, in which I find myself supported by no less an authority than Czerny [1] in a recent publication.

In my operations on the rectum and uterus I have always chosen the median incision, which I have carried well over the sacrum for about six inches, commencing at the anus. The soft parts, after being duly detached from the bone, seem to me to yield sufficiently in either direction to admit of free exposure of the rectum, vagina, and uterus. In Woelfler's parasacral method, where access to the pelvis is sought through the sacro-sciatic foramina, without the removal of any bony structures, a lateral incision is properly recommended, and a Y-shaped incision in Hegar's [2] osteoplastic resection, in which method the coccyx and part of the sacrum are temporarily displaced upward in connection with the superincumbent tissues. I have had no personal experience with these incisions. But the first has in several instances failed to give sufficient room for the removal of the uterus,[3] and the osteoplastic method has been generally condemned as an unnecessary complication of wound-treatment. Furthermore, I think the objections raised against the removal of bone (weakening of the floor of the pelvis, interference with the functions of the bladder and rectum) are merely of a theoretical nature. Kraske and Hochenegg, who have the largest experience with the method, have observed none of these disadvantages. I have myself not heard of any unpleasant symptoms in the cases that have come under my own observation from this source. On this account I have lately adopted the transverse section of the sacrum in preference to the other methods [4] of more, or less complete excision of that part of the left half of the sacrum lying below the third sacral foramen.

These more conservative sections seem to have resulted rather from a willingness on the part of the operator to avoid opening the sacral canal than from a fear of removing too much of the osseous support of the floor of the pelvis. As a cutting instrument I can heartily recommend a strong bone-cutting forceps. In chiselling off the sacrum I have also met with the accident that Hochenegg refers to, splitting of the bone. Further, it appears to me that the sacrum, projecting without any support into the posterior aperture of the pelvis. is not well adapted to the use of the chisel and mallet. The chain-saw and metacarpal saw have been recommended, but I cannot conceive that their application will be more simple, quick, and effective than that of the bone forceps. Besides, the latter has two advantages,[1] it closes the sacral canal by compressing the spongy tissue, and it prevents hemorrhage from the cut surface of the bone itself for the same reason. The latter has occasionally proved very annoying to me when the chisel was used.

It must be acknowledged that the case reported this evening was not a very favorable one for the testing of a new method; still, I believe that such are the only cases in which it will ever be adopted. Where we have a fairly large vagina, a movable and medium-sized uterus, no infiltration of the broad ligaments, it seems to me that vaginal hysterectomy for cancer of the uterus will answer every demand for a simple and safe surgical procedure. Where the uterus is so large that it cannot be reached from the vagina *in situ*, and inversion into the incised cul-de-sac is impossible, laparotomy or laparo-vaginal hysterectomy is indicated. But we all know how unsatisfactory these operations are for cancer when the disease is no longer confined to the organ itself, but has invaded the vaginal wall and the broad ligaments. We know that the vaginal method is entirely impracticable in those cases. The impaired mobility of the uterus, indicating such a condition, and the infiltration of the broad ligaments itself, which can always be detected under anæsthesia, ought to deter us from any attempts in this direction. Even laparotomy is connected with certain disadvantages in these cases. Surgical manipulations low in the pelvis are exceedingly difficult when the ligaments are infiltrated. It should be a rule in surgery to avoid operating at a distance, especially in cases of malignant tumors. The amount of security from recurrence after operation is proportionate to the exposure which the surgeon has been able to make of his field of operation. I am well aware in this connection that the retroperitoneal lymphatics are generally involved only in the last stages of cancer of the uterus, but at several of the sacral hysterectomies now on record a few lymphatics have been found infiltrated and have been removed, which would otherwise have escaped detection. The only way of fulfilling the indication just alluded to is to approach the organs of the pelvis on the plane in which they lie. The anatomy of the pelvis teaches us that this can only be accomplished by entering the pelvis from behind, the only bony resistance which we meet here being the lower part of the sacrum and the coccyx.

For the removal of tubes and ovaries the sacral method does not seem to have given satisfaction in the few cases in which it was employed, especially where there were many adhesions. In my own case much time was sacrificed in locating and separating the single adhesion between the uterus and the sigmoid flexure. Where tubes and ovaries are matted together and adherent to the intestines, the cul-de sac perhaps obliterated, it will be the next thing to an impossibility to operate by the sacral method. For these cases laparotomy alone is indicated. There is no need of getting at the seat of disease so thoroughly, and of such close inspection as in malignant disease. For the evacuation of pus in the pelvis, however, and the treatment of allied conditions, the sacral, or even the parasacral, method might be advantageously employed. I have lately seen a suppurative circumscribed pelvic peritonitis where, as the result of bursting

[1] Maass: Deutsche Zeitschrift für Chirurgie, vol. xxxii., p. 233.

of the abscess into the rectum and operative interference from the vagina for drainage, a recto-vaginal fistula has persisted for some time, causing much discomfort by the passage of fecal matter and flatus through the vagina, with no tendency to heal. In this case the sacral method has forcibly suggested itself to me as the safest and least disfiguring means of closing the fistulous opening in the rectum. Hochenegg[1] has even extended its application to cases of atresia of the anus, of prolapse of the rectum, and of sacral tumor, all of which he has operated on with more or less success by the sacral method.

The immediate results of the sacral method for extirpation of the uterus are, I think, encouraging. Terrier and Hartmann[2] have collected 23 cases with 7 deaths. Adding my own, and 2 which Dr. F. Lange has kindly permitted me to mention, in which the patients have recovered from the operation, we have 26 cases with 8 deaths, 1 from shock, 2 from pelvic cellulitis, 3 after ligature of one of the ureters, and 1 presumably from iodoform poisoning. In one case no autopsy was made.

I will not detain the Section with the usual analysis of these cases. Several of them at least are not attributable to the operation itself. Considering the class of cases we are dealing with—with few exceptions cases of far extended malignant disease of the uterus that have been frequently considered beyond the domain of legitimate surgery—I think the sacral method may claim precedence of laparotomy in cases of cancer of the uterus where the growth is no longer confined to that organ itself.

THE REMOVAL OF SUPERFLUOUS HAIR BY ELECTROLYSIS.[3]

By FRED. J. LEVISEUR, M.D.,

DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITALS AND ST. BARTHOLOMEW'S DISPENSARY.

We are called upon to perform the operation of permanently removing superfluous hair not always in order to satisfy mere vanity or the common desire to please, but very often in order to remedy an evil which, trifling as it may appear, is a constant source of serious inconvenience, even great mental suffering. The young girl who deeply grieves at seeing the bright prospect of her life sadly spoiled by the appearance of a disfiguring hirsute growth on her face, and the middle-aged lady who, being affected in a like manner, goes about heavily veiled, avoids all social intercourse, and becomes more and more irritable, morose, and despondent; these are types of easy recognition and rather frequent occurrence. These unfortunate persons generally fall an easy prey to quacks or the unscrupulous venders of some magic depilatory. Let me state from the outset that as yet I have not met with a single case which had not been made worse by some previous treatment or interference at the hand of the patient. A pair of scissors is usually the first handy instrument which is used to cut off the offending hairs. Then perhaps the hairs are rubbed off with a pumice-stone-like substance which is in the market for this purpose. The depilating forceps may come next, or if the lady is of a more energetic disposition she may apply a resinous plaster in the manner of the French "calotte." After this plaster is made to adhere firmly to the skin it is pulled off, removing all the hairs, which come away with the plaster very much in the manner as did Hercules's skin with Nessus's shirt. The various caustic depilatories remain now for a trial. They generally contain one of the following substances: sulphuret of barium, sulphide of sodium, sulphide of lime, and tersulphuret of arsenic or orpiment. While it may be admitted that these remedies in exceptional cases reach the bottom of the hair follicles and thus effect a cure, it must be stated that in the majority of cases they do more harm than good. The hairs reappear, and in addition the epidermis becomes rough, red, and irritable. After all these efforts have proved in vain some of these women will resort to the razor and become proficient in the masculine art of shaving. *Ce n'est que le premier pas qui coûte.* If a lady is once accustomed to shave herself she will, as a rule, become reconciled to her fate and not apply for further treatment.

The removal of superfluous hair by electrolysis is the only operation which is at all certain of success. It was first used by Michell, of St. Louis, and afterward by Hardaway, Piffard, and other American physicians. The mode of procedure, as is well known, is as follows: The patient being placed opposite a good light, with the head resting in a comfortable position (I use a barber's chair for this purpose), a fine needle or a jeweller's brooch, connected by means of a suitable holder with the negative pole of a galvanic battery, is introduced down to the bottom of the hair follicle by keeping the needle parallel with the direction of the hair. The circuit is then completed by the patient grasping the positive pole tightly. The chemical action of the caustic alkali which is developed at the negative pole destroys the hair papilla. Besides this there are, I believe, certain indications which point to the fact that a peculiar retrogressive change begun under the electrolytic current is kept up for some time after the latter has been discontinued.[1] All this is very simple from a theoretical stand-point; but the practical success of the operation depends upon numerous little details to which it is absolutely necessary to pay close attention. In the first instance, the armamentarium should be complete It consists of a galvanic battery, a milliampèremetre, a rheostat, a needle-holder, a sponge-electrode, some fine needles or jeweller's brooches, and a depilating forceps. Any ordinary battery will do the work, but experience has taught me that twelve to fifteen simple Leclanché cells are superior to all the more complicated apparatus. Never should the operation be attempted without a milliampèremetre.

In an article on electrolysis, published in Dr. Unna's *Monatshefte für praktische Dermatologie*, vol. x., No. 7, I have pointed out this fact, and never since have I let pass an occasion to emphasize it again. As regards the needle-holder, the one which I devised some years ago has proven its general utility. It is constructed so that the needle can be inserted at an angle, it has no separate screw nor clasp, is light, and enables the operator to feel his way, so to speak, into the follicle. Needle-holders which have an attachment for closing and interrupting the current should not be used, since they cause sudden shocks and produce very unpleasant sensations. It is advisable to let the patient herself close and interrupt the current by tightly grasping the electrode attached to the positive pole. Before beginning to operate we connect both poles—sponge and needle—and then by aid of the rheostat (I use a carbon water rheostat) make the milliampèremetre register 10 milliampères. To this is afterward added the resistance which the body of the patient offers. This amounts, with our arrangement, to about 8 to 9 milliampères. We consequently use a current of 1 to 2 milliampères. During the operation all the cells of the battery are at work and the internal resistance, *i.e.*, the resistance in the battery, about equals the external resistance, *i.e.*, the resistance offered by the rheostat, the electrodes, the body, etc. This arrangement guarantees the best results. If the needle is introduced into the hair follicle and the current closed, twenty seconds will suffice to destroy the hair, which will be found to be perfectly loose, and which has to be removed at once by forceps. During the electrolytic action small air-bubbles and minute quantities of whitish sebum will often appear at the orifices of the hair follicles. I do not think that these simple effects of the chemical action of the electrical current have any special significance. The operation is uncomfortable, it is true, but there are few patients who declare it to be seriously painful or unbearable. A twenty per cent. salve of cocaine in lanolin, thoroughly rubbed

[1] Wien. klin. Wochenschrift, 1889, No. 26.

[2] Terrier et Hartmann: Annales de Gynécologie, Août et Septembre, 1891.

[3] Read before the Metropolitan Medical Society.

[1] Dr. G. H. Rohé, Medical Record, September, 1888.

into the skin, enables even very sensitive patients to undergo the operation with ease. I am well aware of the fact that the cataphoric action of the electrical current has been used to render the skin insensible. My experience in this regard is rather limited.

An accident which has lately been reported has strengthened the prejudice which I have against making pass into the circulation of the blood a solution of cocaine without knowledge of its mode of absorption and without means of an accurate doseage. How many hairs can be removed in one sitting, and how many hairs will come back afterward? These questions are constantly asked. I have made it a rule to remove as many hairs as possible in one prolonged sitting, often from fifty to a hundred. These sittings are repeated in intervals of a week to ten days. Provided the operation is done with care and skill no more than five to ten per cent. of the hairs will come back Immediately after the operation the patient's face is washed with hot water, to which some alcohol may be added. The redness and wheals which the operation is likely to produce generally subside in a few hours, but is followed by an inflammatory process in and around the hair follicles. This inflammation lasts a day or two, in some cases even longer. In one of my cases small superficial abscesses appeared the third day after the operation. In order to avoid all such unpleasant complications I prescribe the following salve:

℞. Lanolini,
Ungt. aquæ rosar ..... āā ʒ ss.
Hydrarg. bichlor. corros..... gr. j.

This is to be applied at night and washed off in the morning, and has proved to be an excellent antiseptic measure. It is best only to extract the coarser and more deep-seated hair and to leave the lanugo hairs alone. If these directions are followed no perceptible scars will result and an absolute cure will be effected.

Some time ago there came under my observation the exceptional case of a lady on whose chin a keloid was produced by the electrolytical treatment for the removal of superfluous hair. The lady told me the amusing fact that another physician had tried to remove this keloid by electrolysis.

Let me touch, in conclusion, upon the very interesting question of the etiology of hirsuties. Virchow, Ecker, Bartels, Waldeyer, Unna, and others have advanced various well-known theories. Dr. Geyl, of Dordrecht, has tried to show of late, in a very clear and impartial manner, that universal as well as circumscript hirsuties is the result of the persistence and continued growth of a part or the whole of the fœtal or primitive hair, and that this deformity, as it were, is a pure atavism in Darwin's sense. As regards facial hirsuties, in women particularly, Dr. Geyl claims that it usually makes its first appearance about the time of puberty or of the menopause, both periods when all the cells of the human organism are in a peculiar state of activity. A so-called sexual hirsuties (around the pubes and axillæ) is, in the majority of cases, combined with the facial hirsuties. The beard which grows on a woman's face is equivalent to the beard of a man only in a secondary manner; both have their origin in the hairy condition of the face of our primeval ancestors. These theories are in so far of practical interest, as they confirm the opinion that an ordinary irritation produced, for example, by mercurial ointment, moist dressings, a blister, etc., will not cause a true hirsuties. Lanugo hairs may under these conditions grow to an extraordinary length, but will not be transformed into the coarse and deep-seated hairs with which we have to deal. On the other hand, if a person has a slight degree of general or circumscript hirsuties, or if there exists a hereditary tendency, any local irritation is liable to stimulate the hair into vigorous growth. Electrolysis itself decidedly acts as an irritating measure, and if we remove only a small number of hairs at a sitting, we will make very slow progress, if at all, and our patient will be sadly disappointed.

Clinical Department.

AN ODOR IN INFLUENZA, AND COEXISTENCE OF THE DISEASE WITH OTHER INFECTIONS.

By E. F. FROST, M.D.,
WOODSTOWN, N. J.

While attending, about two years ago, a family of eleven, all down with the "grippe," my attention was called by the mother to a peculiar smell or odor which she described as most disagreeable and offensive, and which she attributed to the disease. They not being particularly careful as to their personal hygiene, I paid no attention at the time to the matter. Subsequently, I was called to attend a man, aged thirty, of Irish descent, who, though about the house, suffered with fever and attending symptoms of aches and pains, cough, and muco-purulent expectoration, about whom there was so strong and offensive an odor that the whole room in which he lived was strongly scented. From his occupation as a farmer, I thought, at the time, that the odor was probably incidental to his calling, and that he had possibly been working in an unclean hen-house, or possibly in musty grain. Soon after, a niece of the above was stricken with the disease, and in her case I noticed the same odor. From that time to the present, I have paid close attention to this symptom, and have noticed its constancy in those cases of undoubted identity as cases of the epidemic, and have found it most marked in patients of Irish descent; but less marked, yet present, in some of those of non-Irish descent.

The odor has the same characteristic in all the cases, namely, the smell of "blue musty meal," in the words of one patient; to my nose, a mixed odor of a foul hen-house and musty meal. The odor was particularly noticeable in the clothing, the sweat, the sputum, in one case in the vomit, and in nearly all cases the air of the sick-room was most foul from the odor.

It is with considerable hesitancy that I write of this matter, but I feel sure of my ground in that the odor is distinct from the ordinary smell of fevers, and that it is, when present, characteristic of the disease. In fact, so true has this been in my experience, that when, at the first meeting with a patient having the odor, a snap-diagnosis was made, the diagnosis has been confirmed by the history, the concurrent symptoms, and progress of the case.

In what follows I wish to speak of several cases in which the "grippe" has been complicated with another disease, concurrent, not intercurrent, and of the influence one disease exercised on the other.

The first case was that of a child, twelve years of age, of delicate constitution, of keen intelligence previous to her attack of the "grippe." I found her about the house with a fever of 103° F.; pulse, 120; cough; lungs full of râles both moist and sibilant; dulness at the apex of the right lung; expectoration muco-purulent; night-sweats profuse; odor above mentioned distinct. Irish parentage. History of phthisis on the mother's side. Treatment with tinct. aconite, rad., gtts. ij. every two hours, did not reduce the fever, nor the rate of the pulse. The fever persisting after trying spts. etheris nitrosi, hydrobromic acid, quinine, antifebrin, antipyrine, I, carefully watching the case, gave her two-drop doses of aconite every five minutes for an hour, without results of any kind. The next day, soon after leaving her, I was summoned to her, as she was "in a fit"—so the message ran. I found her suffering from an hysterical attack, and caught her forcing her fingers down her throat to produce vomiting. Firmness, and exposing her deception, soon relieved her of her "fit," but still there was the same fever and high pulse. The next day, she was bed-fast, unconscious, with at times the whole body suffused from temporary vaso-motor paralysis. A consultation was

held the same day, and death occurred on the next, the patient not having regained consciousness. The vomit during the hysterical fit was most offensive from the peculiar odor, and was so for months afterward, some of it having been preserved in a sealed bottle. Diagnosis, tubercular meningitis.

In this case, no doubt, the presence of the influenza aggravated a dormant tuberculosis.

Again, in a family of four adults, there was in three of the cases, along with the influenza, an accompanying sore throat. The fauces were congested, the arches and palate scarlet, but the tonsils were not swollen, though red; no coating. In the other case there was only a slight sore throat without influenza. In two of the three both lungs were congested, and in one of the two there was lobular consolidation. The soreness of the throat persisted for several days. I traced the sore throat to a case in the neighborhood, of a child sick, about fourteen days, with what was decided by the attending physician to be diphtheria. One of the four of my patients had been to see the sick child and to help the family in their trouble. Moreover, everyone about the neighborhood who had been in to see the sick child suffered from the sore throat. The child was said to be red all over.

Here we have, then, the sore throat of scarlet fever, in adults, aggravated and persisting, probably through the influence of the influenza.

Again, I was called to see a man, aged about sixty five, Irish nationality, suffering from chills, high fever, pains, cough, râles, expectoration, etc. Aconite and ammonium carb. relieved him soon, when suddenly there was another day of high fever, lasting all day and most of the night; no cough, no râles, no dulness, no pain. The time of onset of the chill was not carefully noted, but it was evidently about noon, the following fever being much more severe every other day. In this case the peculiar odor was so strong, the whole room and bedding being saturated, that it was a relief to escape from its presence. Quinine in large doses at 9 A.M. and 9 P.M., daily, relieved in a few days, but there followed a very painful orchitis. On the cessation of the paroxysms there was no further manifestation of the influenza, there being no cough and no râles. There was, however, profound depression, and even a slight melancholia.

In this case we evidently have the influenza poison modified by the paludal poison, to the extent of aborting its full manifestation; yet the duration of the hyperpyrexia was greatly lengthened.

In the previous cases the influenza undoubtedly aggravated the tubercular and scarlatinal poisons, whereas it, in its turn, was rendered quite impotent in the presence of the paludal miasm, although the antagonism developed a high reaction.

Such evidence, if well founded, I consider of the greatest importance to the study of the relations of infectious diseases to each other, and it is in the hope that study in this direction will result in some benefit, that this matter is thus presented.

The Fasting Crank.—Signor Succi has come to the conclusion that his professional reputation is at stake through the recent starving achievement of Monsieur Jacques, as he is now trying to beat the record by a fast of fifty-two days at the London Aquarium. It is a strange comment on this latter-day civilization that men should be able to make a living by starving themselves before an admiring public.

Suicides in Paris.—The official report shows that 890 people committed suicide in Paris during the past year. 243 of whom hanged themselves, 205 were drowned, 164 asphyxiated, 138 shot, 65 jumped from windows, 33 were poisoned, 24 stabbed themselves, 5 jumped under moving trains, and 13 left this sphere by various other routes. Among the drowned and window-jumpers the majority were women.

Progress of Medical Science.

Tannin in Mucous Plaques.—Dr. Thiery (*Gaz. méd. de Paris*, No. 9, 1891) says application of tannin several times a day to syphilitic moist papules, hypertrophic mucous patches in the mouth, and lesions of like nature about the anus, cause speedy healing, and is further to be recommended for its freedom from harm.

Bacillus Viridans is the name applied by Dr. Symmers (*British Medical Journal*, December 12, 1891) to a micro-organism which he has discovered in vesicles of herpes labialis. The microbe, which is of the chromogenic variety, occurs either as a rod or thread form. Free spores do not occur as a rule, but cylinders filled with spore like bodies were obtained after influencing the growth of the bacillus by means of antiseptics. The microbe grows luxuriantly on many different nutrient media. The pigment has not yet been isolated in a pure form. It shows green by reflected light, straw-yellow by transmitted light. It changes with age to sienna, and finally a crimson tint is added. The bacillus is differentiated from that of Frick by its power to liquefy gelatine, and from the bacillus fluorescens liquefaciens by the formation of threads and spores, tendency to grow out into filaments, etc. The pigment was shown not to be pyocyanin by its insolubility in chloroform.

Chyluria.—Chyluria is not as frequent here as in India, still now and then a case is encountered, and while there is no drug known to be especially efficacious in its treatment, it is of interest to read in the *Indian Medical Gazette*, December, 1891, that Dr. Walsh has secured good results from gallic acid, gr. xv. thrice daily, together with two-grain thymol pills. Gallic acid is not a new remedy in this disease, but the thymol was added because it has been found to be an excellent anthelmintic. In a case reported the chyle disappeared from the urine, and no filariæ could be longer found.

Contribution to the Histogenesis of the Papillary Cystomata of the Ovary.—Dr. Williams publishes an article under the above title in the *Bulletin of the Johns Hopkins Hospital*, December, 1891, from which the following conclusions are drawn: 1. The Graafian follicle. This is probably the usual point of origin for the development of these growths; and according as the membrana granulosa is ciliated or not, so the growth will be of the ciliated or non-ciliated variety; and according as the affected follicles grow within the folds of the broad ligament or not, so the growth will be intraligamentous or not. 2. The germinal epithelium. This is the most frequent, and perhaps the only, source of origin for the superficial papilloma, and probably is frequently the starting-point for the usual form of the multilocular papillary cystomata. 3. The tubal epithelium. From a consideration of the conditions in Case I., it is probable that some cases are developed from ingrowths of the epithelium of the tube into the stroma of the ovary. This mode of origin is, however, not yet absolutely proven.

These conclusions tend to prove that the work of all the later investigators in this direction, except those who accepted the Wolffian-body theory of development, has been accurate and of real scientific value; but no one observer seems to have met with all of the different forms of development presented in this article.

Boric Acid in Furuncle and Carbuncle.—Dr. Alison recommends the application of a hot solution of boric acid, forty grammes to the litre, as a friction to the surrounding parts, and as a compress over the lesion, renewed five or six times daily, and always applied hot. Internally, from eight centigrammes to a gramme of the acid are administered daily. It can be taken in wafers morning and night, and is found absolutely harmless for the stomach and other organs.—*Revue générale de Thérapeutique.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, February 20, 1892.

INFECTIOUSNESS OF TUBERCULOSIS.

THE Medico-Chirurgical Society of Glasgow recently presented a memorial to the Town Council of that city calling their attention to the generally admitted infectiousness of tuberculosis, and praying that measures be instituted by them for the protection of the community from its ravages. Among the considerations presented by the committee appointed to frame the memorial were the following:

"1. Tuberculosis is an infectious disease in the sense that in all cases of this disease the one constant and necessary element in the causation is a microbe. This microbe grows and multiplies in the bodies of certain animals and of man, when introduced from without, and in so doing it produces an intensely active poison which is the more direct agent in bringing about the morbid changes in the living structures. There are doubtless other elements in the causation, such as inherited and acquired susceptibility, but the microbe is the only essential and constant one, and there is evidence to show that, without any special susceptibility, it may produce the disease if introduced in sufficient quantity.

"2. As the microbe will not grow except at a temperature almost identical with that of the body, the living bodies of men and animals affected are the great propagating places of it. They are the sources of the supply, and constitute the centres from which the infection is derived. But the microbe is not retained in the bodies of the persons affected. Most of the forms of tuberculosis are characterized by discharges of matter from the affected parts of the body, and these discharges contain the microbe—often in very large quantities. The most frequent form of tuberculosis is consumption of the lungs, and persons affected with this disease almost constantly spit up matter which is loaded with the infective microbe. The spit of such persons when dry is liable to be pulverized into fine dust, and this in its dissemination carries the still living microbe with it.

"3. It is believed that tuberculosis is fairly to be compared, as regards its infectious quality, if not with typhus and small pox, at least with typhoid or enteric fever, although the mode and channel of the infection may be so different as to make it much less obviously dangerous to live in the same house or room with a case of consumption than it would be in the case of one of the well-known contagious fevers. Tuberculosis, however, is much more disastrous in its results than all the other infectious diseases put together."

The committee did not venture to prescribe any particular mode for dealing with the infection, but suggested that the public be authoritatively informed of the harmful nature of all discharges from tuberculous persons, and more particularly from cases of consumption of the lungs, and that they be encouraged to have these discharges rendered innocuous, and also to submit their houses and clothing to disinfection at intervals during the currency of the disease, and again at its close.

This is a very commendable action on the part of the Medico-Chirurgical Society, and it is to be hoped that the Town Council will act upon the suggestion offered. But this is not, as some of the English journals have claimed, the first attempt ever made to educate the people up to a practical recognition of the infectiousness of tuberculosis. The New York Board of Health long ago undertook that task, and much good has already resulted from it.

ST. LUKE'S HOSPITAL.

IT is reported that the Trustees of St. Luke's Hospital have purchased a large tract of land at 113th Street and Morningside Avenue, that they will shortly begin the erection of hospital buildings thereon, and that they will sell the land at Fifth Avenue and Fifty-fourth Street, at which the hospital has been located for so many years. That this move on their part is a wise one, nobody who knows of the institution can doubt. The land which they now occupy is of great value—it is said to be worth two and one-half millions of dollars—while that to which they remove costs but one-fifth of that sum. The institution will therefore be a cash gainer to the extent of two millions of dollars, which, added to the present endowment, will yield an excellent income wherewith to equip and maintain modern buildings.

The new site is one of the most beautiful and healthful in or about New York. It is in immediate juxtaposition to that on which the magnificent new cathedral of St. John the Divine is to be built, while there is much probability that the Bloomingdale Asylum property, just above, will be bought and occupied by Columbia College.

This portion of the city bids fair, then, to be the seat of most important interests, access to which will be made more easy with the improvements in rapid transit.

St. Luke's Hospital deserves the kindest thoughts at the hands of the medical profession. Its management has always been prudent, conservative, and wise. It has aimed to be, and has been, a truly charitable institution. It has not opened a dispensary on Fifth Avenue for the care of people who would drive to it in carriages, but has sheltered with kindness the deserving poor. It has selected its medical officers with care, and has looked upon them as gentlemen, and not as hirelings. Instead of taking the ground that "the hospital confers all, the doctors owe everything to it," this institution has recognized the fact that while the medical men gain very much in knowledge and in position, they do give very much of valuable thought and time in work which may well be construed as charitable.

For these and many other reasons, then, we wish the St. Luke's Hospital all prosperity in its new undertaking.

THE PRESENT STATUS OF THE INFLUENZA QUESTION.

Sometime ago the Medical Record received by cable the first announcement from Berlin in regard to the simultaneous discovery of the influenza bacillus by Pfeiffer and Canon. Both gentlemen have been able to cultivate, on either glycerine-agar, or dextrose agar, the bacilli, the former from the sputum and bronchial and pleural exudations, the latter from the blood, of the influenza patients. These bacilli were stained according to a method previously described in the Medical Record, and then carefully studied. It was found, according to Pfeiffer and Kitosoto, and also Canon, that the influenza bacillus is the smallest bacillus discovered, and, according to its discoverers, can be very easily differentiated by the peculiarity of its growth, inasmuch as each colony is separated from the other and appears entirely isolated. Moreover, the colonies cannot be distinguished with the naked eye, and for this reason it is easy to explain why former observers, having gone through the same *modus operandi*, have probably overlooked the presence of the bacillus when it is now known that only with the aid of the so-called "loupe" can they be recognized.

Boas, of Berlin, commenting on above discoveries, says: "There is a great deal yet to be learned in regard to the bacillus, as it is quite probable that the hasty publication of the discovery by simultaneous discoverers, for the sake of establishing their respective claims, did not give enough opportunities for calm scientific investigation." Boas rightly infers that we do not yet know whether the influenza bacillus is constantly present in every stage of the disease, or only in the febrile stage of the disease, and also whether or not the bacillus is present in the complications of the disease, as pleuritis, pneumonia, otitis media, and affections of the eye.

Then the main question, when do the influenza bacilli entirely disappear from the bronchial secretion, and also from the blood of the patients, has not yet been determined.

Koch has always very properly maintained that all experimenters must prove the pathogenetic character of their micro-organism by being able to infect the human subject or animals by a pure culture through inoculation, and be able to reproduce the same disease, or its manifestations, as the one from which the culture of bacilli was originally taken.

This, Boas maintains, has not yet been proven on man nor on the lower animals.

ONE WAY TO ADVERTISE.

There is a widespread popular belief that physicians do not advertise. This is not, strictly speaking, in accord with the facts of the case. Without advertising one's profession, qualifications, and ability, success is either not attained at all, or comes so slowly and so late that it can scarcely be counted a success. Bringing and keeping one's self before the public is as necessary in a physician's work as in that of any other man—but it is not necessary for him to secure the necessary publicity in the usual ways of trade. The conscientious, painstaking, and wide-awake man who does not forget what is due to himself, neglects no opportunity to do the best he can in every case which comes to him, and thus make his work, his self-denial, his gentlemanliness, all serve as an advertisement of his worth and bring him work.

He who writes, speaks, lectures, operates before bodies of physicians or students is constantly advertising himself whether he will or not. He is making an impression which will influence his professional career in one way or another. There are certain other kinds of advertising which are not looked upon so favorably by the profession when indulged in by one of its members. We shall speak now only of one. For several years past physicians in New York have received regularly each month a package of cards from a "specialist in female complaints." Now, one would not suppose that this form of advertising would pay. A man is not at all likely to refer patients to a specialist who is known to him simply through being bored twelve times a year by the receipt of some cheaply printed cards when he is probably looking for a check in the mail that brings them. That it does pay, however, would seem to be indicated by the fact that imitators have sprung up. Men equally unknown to fame, but who evidently have their printing done in the same office in equally large quantities, and mailed in numbers consistent with the limits of one cent postage. The only explanation of the success of the scheme which presents itself to us is that a sufficient number of cards sift out on the way through the mails and are picked up by the thoughtless, or that enough reach servants and ashmen by way of the waste-basket to return a profit on the outlay. We do not object to a physician's stating his specialty on his card, if he has a specialty and desires to state it, but when he regularly and persistently forces those cards upon you in large blocks, and you have never had the pleasure of an introduction, it would be quite as well to tear them in two before trusting them to the paper-basket.

THE DRUGGISTS' CHECK SYSTEM.

During the recent trial of the ex-medical student Harris, for the murder of his young wife, the wisdom of the check system now employed by most of the reputable drug stores in this city was well shown. Had a single clerk received the prescription, prepared the capsules, and delivered them, it might readily have been claimed by the defence that a mistake had been made by the druggist. As it was, the druggist was able to go on the stand and testify that an assistant had also read the prescription and seen the amount of morphine which it called for properly weighed and dispensed. The importance of the simple precaution in this instance should serve as a warning to all druggists who have not adopted this wise plan whenever prescriptions calling for poisonous drugs are being filled. Only a few years ago a bright young man of this city lost his life by the mistake of a drug clerk, who made him up capsules containing five grains of morphine when five grains of quinine had been called for. The dispenser thought he had the quinine bottle in his hand. It looked like quinine, and if he had suspected himself and tasted it he would have thought it tasted like quinine. He may even have believed that he read on the label "Sulphate of Quinine," but the next day the man who took it was dead, and it was then too late to call a fellow-clerk to look over his shoulder and see if he had

read aright. A physician may prescribe a poisonous dose, but the druggist is supposed to act as a check upon his inadvertence and refuse to dispense it. When the druggist has made the mistake, an assistant should stand between him and the patient. No man is infallible, and in dealing with deadly drugs two heads are to be preferred to the single article.

MADAME LA CHAPELLE.

"Heaven surely ordered, on creation's morn,
This mighty law—that children must be born.
Hence came the science thou dost show so well
With white forefinger, Madame La Chapelle."

Thus sang Dr. Holmes; and undoubtedly he did but justice to the famous midwife. In the *Johns Hopkins Hospital Bulletin*, Dr. William Osler gives an interesting dissertation on Madame La Chapelle, based upon the three volumes of memoirs which were published in 1825. She was born in 1769, and died in 1822, aged fifty-three. For twenty-five years she studied, practised, and taught obstetrics at the Hôtel-Dieu. After this she became midwife-in chief at the Maison d'Accouchement.

The extent of her experience is shown in the table of 15,652 cases which is appended to the first volume of her works. From this we learn that she interfered in 1.73 per cent. of the cases; 15,380 cases terminated spontaneously. Forceps were used but 93 times, version 155 times. Symphysiotomy was still alive, for we find that it was done in two cases where pelves were two and a quarter and two inches in diameter, respectively. The first child died shortly after delivery; the second died with the mother. There was one Cæsarean section in a pelvis one and a half inch in diameter; the mother died the day after delivery; the child lived.

Of 15,380 spontaneous labors, 86 children were deadborn; 522 putrefied. This would give a mortality of 1.71 per cent.

In speaking of diagnosis she gives many interesting suggestions, remarking, for example: "I had always had a bad opinion of a protuberant conical belly, or one very high up in the epigastrium, and rarely has my expectation been deceived. I then have seen the head rest immobile at the superior strait, or the presentation of an unfavorable part." In speaking of artificial dilatation of the parts, she says it is not proper (as the obstetricians and midwives were wont to do) to distend and pull at the orifice of the vagina and vulva. Scientific men at all times have recognized the dangers of such manœuvres, and she quotes from Guillemeau as saying, "above all in this art, says one of the most ancient writers, the midwife will take good care neither to precipitate nor hasten anything, avoiding enlarging the passage for the child by force." "This forced dilatation," she says, "I have never sought to produce."

In the first volume she attacks Baudelocque's classification into 94 presentations of the fœtus, hinting that this was adopted partially out of deference to Solayrès, and afterward maintained from the pride of having taught it so many years. She denounces it as utterly impractical, and purely theoretical, for out of the whole 94, in a practice of thirty years, she herself had met with but 22, and she had never seen a presentation of the neck or trunk.

She gives an excellent classification of these presentations into their genera—vertex, buttocks, feet, knees, face, right and left shoulder; and species (simple and cardinal), such as occiput to the right, left, etc., buttocks to the right, left, etc., and finally varieties or intermediates, imperfect, and inclined positions.

She disapproves of symphysiotomy, and does not advise Cæsarean section except in cases of absolute necessity, and when the child is alive.

She admits that puerperal fever was frequent in the hospital. If she had known the value of puerperal antisepsis there is little doubt that the results of the work done under her skilful care would have equalled those of the present day.

News of the Week.

A Congress of Balneology is to be held in Berlin during the week commencing March 10th. Dr. Oscar Liebreich is the president of the association.

The University of the South, at Sewanee, is about to open a medical department, to be called the "Summer School of Medicine." It is to have a term of five months, beginning in April. The "long felt want" which this new school is intended to meet is not very apparent to the naked eye.

Lord Kelvin is the title which the newly created medical peer, Sir William Thompson, will adopt. That is the name of a river that empties into the Clyde at Glasgow.

Professor Ernst Curtius, the learned Greek authority of the University of Berlin, celebrated recently the fiftieth anniversary of his graduation from the University of Halle, receiving many honors and marks of the love and esteem in which he is held by all Germany, and scholars everywhere.

A Hindoo Woman Physician was recently graduated in Edinburgh. Her name is Miss Jagannadham. She studied first three years in Madras, then two years at the Edinburgh School of Medicine for Women, where she passed her examination most successfully, and obtained the diploma of the Scottish conjoint colleges, thus placing her name on the British Medical Register. She was demonstrator of anatomy during her last session at the Edinburgh School. On leaving the school she spent a year as house physician in the Edinburgh Hospital for Women and Children. Last October Miss Jagannadham went to India, where she intends to spend her life as a medical missionary. She is at present in a hospital in Bombay.

A New Medical College for Women is to be established in St. Paul, Minn.

A Suit Against the New York Hospital for damages sustained by a boy patient who was alleged to have suffered amputation of the thigh as a result of mortification of the leg from tight bandaging for fracture, has been non-suited upon the ruling that no action for malpractice can hold against a charitable institution which uses every care in the selection of competent surgeons to treat its patients.

Lactate of Strontium is recommended in the treatment of albuminuria, in doses of eight grains. It is said to increase the secretion of urine and to reduce the proportion of albumin.

International Congress of Obstetrics and Gynecology.—The following are the subjects which have been selected for set discussion during the sessions of this body in Brussels, September next: 1, "Pelvic Suppurations," to be opened by M. Segond, of Paris; 2, "Extra-uterine Pregnancy," by Dr. A. Martin, of Berlin; 3, "Placenta Prævia," by Dr. Berry Hart, of Edinburgh.

Professor Lépine, of Lyons, will probably be chosen to succeed Professor Regnauld in the chair of Pharmacology in the Paris Medical Faculty.

Prescribing Opticians. — Ophthalmologists in this country will be ready to congratulate, while yet they envy, their brethren in France, in view of a recent decision of a court in Havre. The judge ruled that an optician who gives a patient advice as to the condition of his eyes and prescribes glasses to remedy defective vision is guilty of the illegal practice of medicine, just as if he had ordered remedies or given medical advice without possessing a diploma recognized by the law.

Dr. George W. Ryan, of Cincinnati, recently had the misfortune to fall as he was entering his carriage and sustained a Pott's fracture. His many friends in this city and throughout the country will hope for his speedy recovery.

A Legacy to the Medical Attendant.—The late Prince Louis Lucien Bonaparte left in his will a bequest of $500 to his physician, Dr. Isambard Owen. This is a case in which a prince has set an example worthy of imitation.

Dr. Robert P. Bush, Speaker of the New York State Assembly, is a practising physician. This is his seventh term as Assemblyman.

New York Maternity Hospital.—Dr. George W. Jarman has been appointed Assistant Obstetric Surgeon to the New York Maternity Hospital, to fill the vacancy occasioned by the resignation of Dr. Irwin H. Hance.

The Eleventh German Congress of Internal Medicine will be held in Leipzig, April 20th to 23d. Among the subjects for set discussions are: "Grave Forms of Anæmia," by Drs. Biermer and Ehrlich; and "Chronic Hepatitis," by Drs. Rosenstein and Stadelmann. The Permanent Secretary of the Congress is Dr. Emil Pfeiffer, of Wiesbaden; and the President is Dr. Curchmann.

Prize for an Essay on Temperance.—It is stated in the *British Medical Journal* that the President of the French Republic has offered a Sèvres vase as a prize for the best essay on the following subject: "A Study of the Best Measures to be Taken by the Legislature or by Private Initiative for the Prevention of the Abuse of Alcoholic Drinks, and for the Obviating of its Dangers." The award, which will be in the hands of the French Society for the Prevention of the Abuse of Alcoholic Drinks, will be made in December, 1892. Essays, which must be written in French, should be sent, on or before September 30th, to Dr. Motet, General Secretary of the Society, 161, Rue de Charonne, Paris.

Professor Virchow was recently elected to the presidency of the Berlin Medical Society by 135 out of 137 votes cast, Professors Bergmann and Bardeleben receiving one vote each.

Revue Générale de Médecine, de Chirurgie et d'Obstétrique is the name of a new weekly journal appearing in Paris, under the editorial management of Dr. F. de Ranse.

Congress of Criminal Anthropology.—The third Congress of Criminal Anthropology, in its relations with sociology and biology, will be held in Brussels, August 28th to September 3d.

Medical Society of the Missouri Valley.—The next meeting of the Medical Society of Missouri Valley will be held in the city of Leavenworth, Kan., March 17 and 18, 1892.

Unauthorized Use of Letter-head of Association of Acting Assistant Surgeons.—Dr. W. Thornton Parker, the Recorder of the Association of Acting Assistant Surgeons, United States Army, assures us that the use of the letter-head to which we referred in a recent issue, in connection with the endorsement of a proprietary medicine, is entirely unauthorized by him and that he has demanded its retraction from the firm in question.

New York State Medical Association.—The eighth annual meeting of the fifth district branch of the New York State Medical Association will be held in Brooklyn on Tuesday, May 24, 1892. All fellows desiring to read papers are requested to notify the Secretary, E. H. Squibb, M.D., P. O. Box 94, Brooklyn.

A New Children's Hospital.—The trustees of St. John's Guild have secured a building at No. 157 West 61st Street for a new hospital for children. The hospital is to be free for all the children of the poor without distinction as to color, nationality, or creed. It is intended that other similar hospitals shall be opened in different parts of the city as soon as the requisite funds may be obtained. The Guild calls for contributions to aid it in the establishment and maintenance of these hospitals, which may be addressed to the treasurer, Mr. W. L. Strong, 501 Fifth Avenue.

Dr. Claude M. Jones, of Boston, died in that city a few days ago. He was born in Worcester in 1845, was graduated with honors from Harvard in 1866, and from the Harvard Medical School in 1874.

Typhus Fever in New York.—Within the past week there have been developed in this city 84 cases of typhus fever in Russian immigrants from the steamer Massilia. They were promptly cared for by the Health Department at the North Brother Island Hospital and thus far no deaths have occurred. The patients are impoverished refugees from the Russian famine districts and naturally present the disease in its graver forms.

The Small-pox Epidemic in Milan is finally at an end, thanks to extensive vaccination and revaccination.

Dr. A. H. Paquet, Professor of Clinical Medicine in the Medical Department of Laval University, Montreal, died recently at St. Cuthbert.

Reviews and Notices of Books.

Text-book of Ophthalmoscopy. By Edward G. Loring, M.D. Edited by Francis B. Loring, M.D. Part II., Diseases of the Retina, Optic Nerve, and Choroid. 8vo. pp. 253, with 8 Colored Plates. New York: D. Appleton & Co. 1891.

This admirable section of Dr. Loring's work on ophthalmoscopic diseases appears three years after his death, which occurred in April, 1888. Part I. appeared in 1886, and was devoted to the normal eye, determination of refraction, diseases of the media, physiological optics, and theory of the ophthalmoscope. The present section is published by his brother, from original matter by the author, without addition or correction. The plates, too, are original with the author, and most of them are attested to by his signature.

One cannot go through the pages of this work without being arrested by the singularly broad views of disputed theories in ophthalmological matters, and by their clear and well-defined expression. Take, for instance, the paragraph on page 20, on the "Changes in the Light-streak upon the Centre of the Retinal Vessels." Where in the literature can one find so clear an elaboration of what this may mean? Without going into the argument of the author, it is enough here to refer to his opinion as to the size and shape of the retinal vessels influencing the light-streak, its color in different diseases, as in glaucoma; its alterations of intensity and brilliancy, due to an altered index of refraction, as has been said to occur in the retinitis of Bright's disease.

Further, the author discusses in a most interesting way alterations and disappearances of the light-streak in disturbances of the vitreous, concussions and blows upon the eye and head, mitral regurgitation, and aortic insufficiency. The light-streak is wanting in actual separation of the retina, but it is modified and altered, as to size and reflex, in commencing detachment of the retina.

Under the head of retinal circulation the author has written somewhat in detail on the subject of the visibility of the circulation; and he has done this on account of the retinal vessels furnishing the only possibility of accurate study of the circulation, both on account of their lying behind transparent media, and because of their smallness of calibre, and delicacy of wall. Jaeger may be said to have first described this curiosity, but many observers in Germany, England, and America have reported graphic cases. The vessels seem to be nodular, as if the blood travelled in segments. The stasis may be due to embolism, or to retro bulbar neuritis. While in all the cases there is a reduction of vision to a quantitative perception of light, the nourishment of the retina seems to be maintained, for nearly normal vision returns on the re-establishment of the retinal circulation. Some of the phenomena of hysteria and of hystero-epilepsy correspond to those here adduced.

The chapter devoted to certain forms of inflammation of the optic nerve, and more particularly the pages on papillitis, or "choked disk," will be of especial interest to the student of ophthalmoscopy. Dr. Loring's pupils can never forget the enthusiasm with which he described the various forms of discal disease by the aid of charts and crayons. His so called "Medusa head," well illustrated typical choked disk. He reiterates in this work, in a most persuasive and eloquent manner, just what choked disk is, and reaffirms an opinion advanced in 1882, that "it is not simply a vaso motor disturbance, which leads to inflammation and stasis on account of the anatomical condition of the parts affected, but that it is a true neuritis, an irritation of those fibres of the fifth pair which not only regulate the blood-supply in the vessels, but which also maintain the healthy processes of waste and repair of the elements of the tissues themselves. Furthermore, that the irritation is conveyed, not by the isolated fibres of the sympathetic system, but through the agency of the trigeminus, and especially of the recurrent ophthalmic branch." Von Graefe's theory of increased intra-cranial pressure, whose influence extended to the cavernous sinus, was perhaps the first important theory of the phenomenon. Galezowski maintained that choked disk was a neuritis consecutive to intra-cranial inflammation, and was propagated by continuity of tissue; hence, that it was always a descending neuritis. The author would have it plainly understood that "choked disk is choked disk, and may come from a multitude of causes," such as retro-bulbar neuritis, neuritis descendens, perineuritis of the optic sheath, intervaginal hemorrhage, neuritis from uterine disorders, tumors of the brain, syphilitic and rheumatic neuritis, hydrocephalus, etc. Under the topic of uterine disorders, the famous case of premature delivery to save sight is requoted at length, and it is cited as the first case of such attempt on record.

Part II. surpasses in interest its predecessor, in so far as it publishes the peculiar views of the author on some of the abstruse physiological and pathological phenomena of the eye. It is a matter of profound regret that this part finishes all the material left by the late Dr. Loring.

Pulmonary Tuberculosis. By R. W. Philip, M.A., M.D., F.R.S.E., Fellow of the Royal College of Physicians of Edinburgh; Assistant Physician to the Royal Infirmary; Physician to the Victoria Dispensary for Consumption and Diseases of the Chest, Edinburgh. Edinburgh and London: Young J. Pentland. 1891.

This etiological and therapeutic work, based on experimental investigation, embodies results of research begun in 1885, and is in part reprinted from the "Transactions of the Ninth International Congress," where the first division was read by the author in 1887. An Appendix treats of the nature of the toxic product—an improved method for the demonstration of bacilli in tubercular sputum—and clinical method for staining the tubercle bacillus. Twenty one of the fifty-five pages of the octavo volume are taken up with record tables of experiments on mice, frogs, etc., undertaken with the view of elucidating the actual cause of death from phthisis, or the *modus operandi* of the tubercle bacillus toward this end. The result of these investigations leads the author to believe that, in all probability, the fatal propensities are attributable to a power possessed by the bacillus of elaborating new products which are afterward absorbed. Treatment is considered in reference to the stage of the process. Thus in the catarrhal, or pretubercular, period the therapeutic indications are essentially prophylactic. In the stage of invasion by the tubercle bacillus, which may be supposed to have begun developing in the catarrhal products, as in a cultivation medium outside the body, such measures are called for as will render the tissues less suitable media for the growth of the bacillus.

In the stage of elaboration and absorption of toxic products such remedies as can be proved antagonistic to them should be made use of. The author's experimental results point to atropine as one of these. This little volume is well worth reading by all those interested in the great subject.

Increase of Insanity in France.—Insanity has increased so in France that asylums can no longer hold the lunatics. The *Assistance Publique* has, therefore, decided to place some of the insane paupers who are harmless with peasant families, just as it now puts out pauper children.

Women in Swedish Universities.—The higher education of women is making great progress in Sweden. The number of women students in the universities there is now large and is constantly increasing. There are eighteen women students in the Upsala University, thirteen in Lund, and eight women are studying medicine in the Carolinske.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, January 7, 1892.

A. L. Loomis, M.D., President, in the Chair.

Final Results in Tubercular Ostitis of the Knee in Children; Analysis of Three Hundred Cases.—Dr. Virgil P. Gibney read the paper. About twenty patients, numerous drawings, and several forms of dressing apparatus, were shown in illustration of the subject. The cases analyzed had been seen in the Hospital for the Ruptured and Crippled, the New York Polyclinic, or in private practice, the earliest dating back to 1868. With the assistance of Dr. Fitzhugh and others of the staff, he had during the past eighteen months found the names of 499 patients who had applied for treatment of tubercular ostitis of the knee, and of this number he was able to give an analysis of 300.

By tubercular ostitis of the knee was at present understood a tuberculous inflammation of the lower epiphysis of the femur, upper epiphysis of the tibia, primarily, and a chronic inflammation by contiguity of the immediate joint structures.

After giving a graphical clinical picture of the three stages of the disease, and impressing the necessity for its early recognition and management, the author took up the analysis of the 300 cases in detail, adding thereto what facts were known of the other 200 cases. There were 223 females, 276 males. In 239 the right knee was affected, in 235 the left. Of 387 cases the disease developed in 197 before the fifth year; in 142 between the fifth and tenth years; in 39 between the tenth and twentieth years, and in 9 after the twentieth.

Much had been written about involvement of other joints, and fear had often been expressed that the disease might break out elsewhere. But of the 499 cases there were only 16, or three per cent., wherein other joints or bones were involved. Eight of the 16 had Pott's disease of the spine, 2 ostitis of the hip, 1 disease of the ankle, 1 of the elbow, 1 of the wrist and shoulder, 2 in the other knee, 1 in the other knee, elbow, and shoulder.

Of 300 cases, 140 had abscess, 160 never had abscess. Forty had died, the cause of death being: 6 of tubercular meningitis, 14 of exhaustion after prolonged suppuration, 3 of phthisis, 2 of dysentery, 2 of amyloid degeneration, 12 of intercurrent affections not connected with the knee disease, 1 of shock following excision. It was fair to assume that 22 died as a result of the disease, causing exhaustion from suppuration, tubercular meningitis, and amyloid degeneration, which gave a mortality of $7\frac{1}{3}$ per cent.

Treatment.—All the cases had been subjected to one of three kinds of treatment: 1. The purely expectant, which meant the treatment of symptoms with little reference to signs or correction or prevention of deformity, but an effort to relieve exacerbations, and during intervals the irregular use of apparatus, frequent changes in apparatus, no single form being used sufficiently long to test its efficiency. 2. Fixation treatment, which meant the continuous use of some apparatus, whether plastic or steel, some of which partially and some completely immobilized. 3. The protective treatment, which meant immobilization of the joint until all acute signs had subsided and convalescence could be safely predicated, the use of an apparatus which prevented concussion or trauma of any kind, whether in the shape of a perineal crutch or axillary crutches. He did not class under protection splints the ordinary extension apparatus, because the adhesive plaster with which traction was secured slipped, the skin and deeper tissues themselves moved, so that jar or trauma was not prevented. Under protection was also included correction of deformity by apparatus, manual force under anæsthetic, or incision. They had depended largely in protective treatment on the Thomas knee-splint, which was simply a perineal crutch with high shoe on the sound foot.

It had been exceedingly difficult to draw a sharp line between the three methods described. In a general way it could be stated: 71 cases had been recorded as having been under the expectant treatment, 3 deaths, 2 of which only were due to the disease; 5 came to excision, 3 to amputation, and 60 remained with fair results; 190 cases received the fixation treatment throughout. Of this number there was 35 deaths, 20 of which were traceable to the disease itself, 9 came to excision, 1 to amputation, and 145 remained with more or less fair results. Only 39 had been subjected to the protection of Thomas treatment. Two had died from causes in no way connected with the disease; 37 remained with good results.

Of 60 cases under the expectant plan, 44 had motion, 16 no motion; of 145 cases under the fixation plan, 113 had motion, 32 no motion; of 37 under the protection plan, 34 had motion, 3 had no motion. This showed that motion was more frequent in those treated by the protection plan. Tables were given showing the amount of motion. In 16 where abscess occurred, the extent of motion was 90°; where no abscess had occurred, 25 could voluntarily move the leg over an arc of 90°. Relapses had not been very frequent. Among abscess cases, in only 4 had relapses occurred in a period from seven to twenty years; among the non-abscess cases, 6 had had relapses.

The question was often asked whether patients would not require some kind of apparatus the remainder of life. Out of 300 only 36, or twelve per cent., had continued to wear some kind of support.

Deformity.—Of all cases, whether anchylosed or with motion, having had abscess or not, 150 presented subluxation of the tibia, as against 48 in which there was no subluxation. Only 2 presented complete luxation. In 183 cases where the condition of the patella was noticed, in 124 it was movable, in 59 no motion. The tables showed that of 227 cases only 15 got well, with a deformity at an angle under 135°, and 141 presented an angle of deformity of not less than 165°. This enabled them to walk with the limb practically straight and with scarcely any appreciable deformity. The protection treatment gave the largest percentage of good results so far as position was concerned; fixation next, and the expectant plan third.

Of 116 cases analyzed as to increased lengthening, sixty-two per cent. showed increase. Two or three cases were shown which illustrated the danger of operating in early life, the resulting shortening, etc., being very marked.

In conclusion, the author wished to present in as strong terms as possible the value of what was known as the protection treatment. It was efficient, and in early cases would yield almost perfect results.

Dr. L. A. Sayre, and others who discussed the paper, expressed their great pleasure in listening to the reading of it, and were of the opinion that it would constitute a landmark in statistical studies of the treatment of tubercular ostitis of the knee. Dr. Sayre related an amusing and instructive incident occurring in his early practice, to show that old therapeutic notions were not always the best. In this particular instance it referred to the ancient fear of opening cold abscesses connected with joints. He agreed with the author of the paper regarding the value of the protection treatment, but thought that something should be added in order to obviate the trauma produced in the joint by muscular spasm. He overcame this by counter-extension through means of adhesive strips.

Dr. Charles McBurney was pleased with the results obtained by the author with the conservative treatment. He seemed to think, however, that there was danger, in some instances at least, of carrying this treatment as opposed to excision too far. Where operative measures were adopted, of course it should be with special precaution to save the growing portion of the limb. His

own feeling was that, as surgeons should advance in operative procedures, they would yet approach the results of the conservative method. They would give up, to a certain degree, the complete excisions formerly practised, and come down to partial excisions, using them in such a way as to preserve as far as possible the length of the limb. He had seen a good many cases treated conservatively which had apparently passed beyond hope, yet after resorting to excision there followed rapid restoration to health. This quick release from bed, apparatus, and expense spoke much in favor of excision.

Dr. Whitman thought it should be remembered that the statistics given by Dr. Gibney were not of a single kind of treatment, and for that reason they were the more valuable. They had not been cited in opposition to operative measures. But it should be remembered, also, that there was no operative method which would enable one to dispense with careful and persistent management of the kind related in the paper. Failure to give cases sufficient subsequent attention might account for so large a proportion of relapses in cases operated upon by general surgeons. The opening of abscesses, etc., was not neglected by orthopedic surgeons.

Dr. H. L. Taylor thought the general surgeon should be impressed by the lesson taught by the statistics, that there were fewer fatal cases from prolonged suppuration, etc., attending the conservative treatment than they seemed to think. He approved of protection and immobilization, but agreed with Dr. Sayre that there should also be counter-traction to overcome trauma from muscular spasm. This he would effect by light weights or adhesive plaster. It might be effected in part in the standing posture by the weight of the leg, while the patient was wearing the Thomas splint, with the shoe on the sound foot elevated.

Dr. Reginald H. Sayre impressed the need of preventive or protective treatment even where operative measures were resorted to. He agreed with others who advised traction as well as protection against the trauma of jar.

Dr. Gibney made some closing remarks, expressing the opinion that there was not, he thought, much difference between him and the other speakers, including even Dr. McBurney. He was not opposed to operations where they were really needed, but amputation or any other operation could not be advised in these cases on the strength of being a short and inexpensive route. Protection and general care should not be neglected subsequently, and the expense of artificial limbs would soon exceed that of cases which could get along without an operation or amputation.

Stated Meeting, January 21, 1892.

Alfred L. Loomis, M.D., in the Chair.

The Elements of Contagion in Tuberculosis.—Dr. T. Mitchell Prudden read a paper with this title, opening the discussion bearing on the question of prevention of tuberculosis. The meeting was under the auspices of the Section on Public Health and Hygiene, Dr. H. D. Chapin, Chairman.

Dr. Prudden presented, in his usual concise and argumentative way, the evidence pointing to the tubercle bacillus as the cause of tubercular phthisis, and the conditions under which its propagation and spread were most likely to take place. While the germ propagated and showed its virulence only in warm-blooded animals, yet it might remain alive outside, especially in the dried state, and after months set up tubercular disease when transported to a favorable soil.

By far the most common mode of transportation or source of contagion was in the expectoration of persons suffering from pulmonary tuberculosis. The dried sputum became mingled with the dust of the air and was inhaled into the lungs. The fact should be impressed upon the public that the tubercle bacillus alone could cause tuberculosis, although there were many other contributory conditions. But without the tubercle bacillus this particular affection could not arise, however favorable might be the surroundings, heredity, etc. Vague notions of the cause of tuberculosis should disappear, and all should come to realize that it was due to something definite, to something which we could see, handle, and kill. With this fact impressed upon the mind the public would more readily appreciate the further truth, that the living virulent tubercle bacilli were floating in the dry dust in the air where consumptives made their homes, and that close attention upon and association with such persons, without intelligent precaution, frequently involved acquirement of the disease.

We had learned that what once was considered hereditary transmission of the disease was often nothing but household poisoning, or exposure to the germs of the disease wherever they might exist. The author defined an infectious disease to be one which was caused by the invasion and reproduction within the body of pathogenic micro-organisms. Not necessarily an invasion by bacteria, however. Infection was the condition produced by the entrance and multiplication of pathogenic micro-organisms within the body. An infectious disease was contagious when its contagium, that is, its micro-organism, could under ordinary conditions of life be freed from the body of the diseased person and conveyed to the body of another, and there light up anew the disease. The difference in physical qualities of the contagium, of place, and way in which it was freed from the body and carried to another, would account for much of the mysticism surrounding the term contagious. The fact that such infectious diseases as diphtheria and tuberculosis could be highly contagious or scarcely at all, so depended upon the care taken by the victims or their attendants in disposing of the exudates or discharges.

Along with any legislative suggestions or means taken to prevent tuberculosis, the public must be educated regarding its contagious character. The people should not be allowed to get the idea that methods for its prevention meant ostracism or isolation.

On the Necessity and Possibility of Efforts to Prevent the Spread of Tuberculosis.—Dr. Edward G. Janeway said that in his part of the discussion he would only consider the contagiousness of pulmonary phthisis and certain measures which could at least be attempted in the way of controlling the spread of the disease, as coming from persons already suffering with it. There were to day, he said, only few physicians who hesitated to accept the bacillus tuberculosis as the direct exciting cause of tubercular phthisis. Yet the idea was more or less prevalent that heredity played a most important part. As evidence of the contagiousness of the affection, several cases were related from the author's note book. A father and mother were healthy, one of their children became affected, and then all the others in succession fell victims to the disease. In another instance, a son married a young lady having phthisis, and he, his mother, and brother became affected, although belonging to a family without natural tendency. A lady coming from a family free from phthisis, went to live in a house where a man had died of phthisis, she herself contracted the disease. A family free from tubercular history, father and mother and three children still living; a child in the family, two months of age, was kissed by the daughter of a person in attendance, the daughter having phthisis with bacilli in the sputa, the babe became infected and died with rapid inflammatory disease of the lung breaking down into cavity.

Estimating the number of the living suffering from phthisis as one third the number dying of that disease in any given year, which was certainly within the true limits, he said we would have at any one time in New York, during the year 1890, 16,000 persons with tubercular phthisis. Much the larger proportion were over ten years of age. Admitting the presence of so large a tu-

berculous population, and that the disease was contagious, how was it that so many escaped contracting the disease? The answer lay in powers of resistance. Under certain conditions the resistance became diminished, and then exposure to the tubercle bacilli was likely to lead to tuberculosis.

Speaking of modes of prevention, the author lamented the crowding of population to such an extent as it existed in New York, where, over a given area, the number of inhabitants was very great, which meant under present conditions filth and vitiated air. This was shown by the fact that New York had more cases of contagious diseases comparatively than Philadelphia, which was spread over a much greater ground area There were exceptions in typhoid fever and small-pox, to be accounted for in the former case by the difference in water-supply, and in the latter by New York's better sanitary restrictions over small pox.

Admitting even the probability of truth in the germ theory as applied to tubercular phthisis, every physician should instruct his patients suffering from this affection how to best prevent the spread of the germ. It might be made the duty of the physician to report his cases to the authorities, who should send rules to the family or patient. Third, inspectors might be employed by the authorities to visit reported cases, and instruct patients and friends what measures should be adopted, and to inquire from time to time regarding the carrying out of the instructions received; but a combination of the two former seemed to the writer all that could at present be attempted. There should be explicit printed rules in all necessary languages for distribution by physicians to patients and their friends. He would suggest the instructions include destruction of the sputum; cleanliness about the mouth and beard; not to allow sputum reach the floor or touch beds, and when this happened, to employ thorough disinfection; frequent change of bed sheets, and keeping bed-covers clean; occupying different rooms as far as possible, by sick and well; the sick to sleep alone; hotels should not put the well into rooms which had been occupied by tubercular patients, at least without informing them, and after thorough disinfection. Vessels to expectorate in should be placed in public halls, etc., contain, say water, and be disinfected by boiling water. Marriage with the phthisical might be discouraged.

The Prevalence of Consumption in the United States.—Dr. John S. Billings, of Washington, sent a brief communication bearing on this part of the subject, which was read by Dr. Chapin. The death-rate, according to the census returns, had been 1.6 per cent. per thousand of the population for 1890; in 1882 it had been 1.8 per cent. In both instances the figures were too low, probably, by at least twenty per cent. Taking certain States, in 1890, the rate in Connecticut had been 2.34; District of Columbia, 3.59; Massachusetts, 2 67; New Jersey, 2.34; New York, 2.45, etc. From these data it was quite safe to assume that the whole number of deaths due to pulmonary phthisis in the entire country, during the year, was over one hundred and twenty-five thousand. The death-rate from this cause was greatest in the larger cities.

As to the number of cases of pulmonary phthisis existing at any one time in a given locality, it could only be estimated from the number of deaths. If one estimated the average duration of the disease as two years, there would be two cases in existence for every annual death. In this way we could estimate 11,000 in existence in New York City, 4,000 in Brooklyn, 13,000 in the rest of the State.

Recognizing that the chief means of conveyance of the contagion was the dried and pulverized sputum, Dr. Billings said special attention should be given to caring for sputum and to cleansing floors, etc., of public resorts, but particularly those places where the vicious were accustomed to congregate. At present there was special need for attention in these respects to criminal court-rooms. Here classes congregated who expectorated upon the floor, were dirty in person, yet it seemed to be the general custom to allow such rooms to go uncleansed, or dry dust was swept out, contaminating the air and furniture. This was a frequent source of tuberculosis among lawyers.

Recent Investigations concerning the Contagiousness of Pulmonary Phthisis; what Rules Can the Profession Properly Advocate for the Government of the General Public.—A verbal discussion took place on this subject, opened by Dr. A. Jacobi. He said he would limit his remarks to the prevention of tuberculosis in children. Tubercular phthisis being a contagious disease, the virulent agent must enter from without. Very seldom did any form of contagion, not even diphtheria, arise without there previously being a broken skin or mucous membrane. Recognizing the many sources of exposure to the tubercle bacillus, he spoke warmly against the indifference manifested, not only by the public, but also often by physicians, regarding the existence of an eczema, a diarrhœa, a sore mouth, an abrasion of any kind in children. Especial attention should be given catarrh of the larynx, of the pharynx, of the nose, of the intestinal tract, and other lesions of mucous membranes, and also of the integument. Tuberculosis of the intestinal tract almost always gave a preceding history of neglected diarrhœa. Another point was that children should not take their milk unboiled. All domestics should be examined before being admitted into the household.

Dr. J. West Roosevelt thought the rules to be given the public were, after all, very simple. The question which we had to consider was not the dealing by medical men with sick people, but impressing the public with the duty of simple cleanliness in its most complete form throughout the house. The people should be taught not only to disinfect sputum and to observe cleanliness to its fullest extent, but also the reason why. It was largely a question of ventilation and cleanliness. A patient suffering with phthisis should have a room, every part of which could be scrubbed with soap and water. In sweeping, use damp tea-leaves.

A Question of Seed and Soil.—Dr. Andrew H. Smith said there were two factors to be taken into consideration, one being the seed, the other the soil, and in proportion as we made these facts clear to the public, would our advice for preventing the spread of tuberculosis be followed. When asked why so many escaped when the tubercle bacillus was so plentiful, he answered by illustration, saying that rice sown on the top of a sandy hill would never bring forth a crop; or, prepare a river bottom ever so well, and sow no rice, there still would be no crop. It required the proper seed and also the proper soil to reap a harvest. Applying this to tuberculosis, to prevent dissemination of the seed was very important, yet of equal importance was it to obviate preparing a suitable soil. Every mode of life, every surrounding which depressed the vitality, made the soil better for the germination of the seed. In the country whole families were often affected, which Dr. Smith attributed to small rooms, want of ventilation, and uncleanliness. The town post-office, he thought, needed attention as well as the criminal court-room. Might not the germ be carried in the mail?

Dr. William H. Porter thought far the most could be done in eradicating tuberculosis by feeding properly from infancy up. Yet he would not belittle attempts to prevent the entrance of the germ of the disease in all possible ways.

Dr. C. C. Currier said that, by request of Dr. Chapin, he had searched the literature for any evidence going to support older views, especially that regarding hereditary influence. Baumgarten, who was an eminent authority and familiar with bacteriological investigations, had tried to show, in an article in the *Deut Med. Wochenschrift*, October 13, 1891, that heredity was perhaps a more important factor than inhalation of bacteria. Children who

were, it seemed, most exposed to infection, were not specially subject to tuberculosis, especially that of the lungs. Much testimony of a negative character had been given, such as the absence of tuberculosis among nurses in institutions for pulmonary phthisis, etc. Baumgarten, Rindfleish, and others, claimed and gave some proof that the bacillus tuberculosis could be inherited, and remain latent many years. Considering the possibility of inheriting the disease, it could safely be stated that tuberculous families should not intermarry.

The President, Dr. Loomis, said he hoped any person wishing to take part in the discussions of the Academy would do so. It was not intended to limit the speakers to those whose names were printed on the programme. The only reason why readers of papers had been requested to name some who would participate in the discussion, was that it should be made pointed and more interesting. It was not intended, however, to prevent others from speaking.

Dr. Leonard Weber thought the Academy should formulate some rules bearing on the prevention of spread of pulmonary tuberculosis in line with the discussion of the evening, for circulation by means of the public press, Board of Health, etc.

Dr. A. Jacobi agreed in this suggestion, and the President said it was the intention of the Section on Public Health and Hygiene to again bring the matter before the Academy.

Caution with Care.—Dr. Laurence Johnson said the belief was still common that pulmonary phthisis was a hopeless disease, and if by any regulations physicians were compelled to state to every patient the nature of his affection, many who otherwise probably could be cured would be cast into fatal despondency. He thought the public should be taught that all sputa, no matter what might be the nature of the cough, should be disinfected; that to expectorate upon the floor or anywhere else, except as physicians advised tuberculous patients to do, was extremely nasty.

Opposed to Kissing.—Dr. August Seibert thought one of the examples given by Dr. Janeway showed most clearly the possible evil of kissing. This habit was so common among school-girls as to constitute a serious source of danger in conveying contagious diseases. He had before suggested the propriety of a daily inspection of the throat of school children.

The Public Should be Educated, not Frightened.—The President said that while all the speakers admitted the contagiousness of phthisis, yet to use this term without explanation would be liable to convey to the public the idea that they were in as great danger of contracting this disease as scarlet fever or small pox, which they also knew to be contagious. It was necessary, therefore, to educate the people regarding the extent and manner in which tubercular phthisis was contagious, and not to unduly frighten them. Regarding prevention, he thought the keynote had been struck a number of times during the discussion: it was, in its simplest form, cleanliness. As Dr. Johnson had said, people should be taught that all expectoration was nasty. No gentleman would spit in public. He might find it necessary to use his handkerchief, but he would not be seen expectorating. Teach the people to bathe, to wear clean clothes, to keep their houses clean, get fresh air. We should live more out of doors, as they did in England.

An Important Section.—Dr. Chapin hoped the attendance on the meetings of the Section on Public Health and Hygiene would hereafter be in proportion to the importance of the subjects with which, from its title, it evidently had to deal. He hoped they would be well attended by public-spirited citizens as well as by the profession.

Sir James Paget's Son is an English clergyman, and has recently been appointed Dean of Christ Church, Oxford.

SECTION ON SURGERY.

Stated Meeting, December 14, 1891.

William T. Bull, M.D., Chairman.

Two Cases of Brain Abscess Successfully Treated by Opening the Skull and Drainage.—Dr. B. B. Gallaudet presented the cases. The first occurred in a boy, aged twelve years, who fell and struck the head, causing a depressed fracture. A week after the injury the boy began to be a little stupid and dull. Nothing further was observed until a week before his entrance to the hospital, when several convulsions of the muscles of the right side of the face had occurred. There were no more convulsions after his admission to the hospital. His mental condition was somewhat dull. About two inches above and posterior to the top of the ear there was a small scar; the boy was up and about for four weeks, during which time he showed mental improvement. Then there developed fluctuation over the scar. A small incision let out about a drachm of pus, and afterward more pus came from within the cranium. A few hours later ether was administered, a small portion of eroded bone was removed, pus escaped through an incision into the dura, the hole in the skull was further enlarged, the dura split open, and there at once escaped half an ounce of pus. The cavity within measured nearly an inch in diameter. It was washed out with Thiersch's solution. The boy made a good recovery, his mental condition having again become normal.

The second case occurred in a girl, aged six, who was admitted to the hospital August 29th last, with a history that she had just fallen from the third story of a house, struck her head on the sidewalk, and was brought immediately to the hospital. There were general symptoms of extreme cerebral concussion. Locally a soft hæmatoma was found, extending an inch or more over the right supra-orbital arch; no fracture could be detected by ordinary means, and owing to the extremely prostrated condition of the patient, it was not thought advisable to cut down immediately on the hæmatoma. The patient's condition continued about the same until September 7th, nine days after the injury, by which time the hæmatoma had become larger and the patient had become restless and irritable. A trephining operation was then performed, a pus cavity was washed out, the depressed portion of bone raised and fragments removed; the finger was introduced as far as an inch and a half into the frontal lobe of the brain, where the pus-cavity had existed. The cavity was washed out with Thiersch's solution, and iodoform gauze dressing applied. The patient after some days had completely recovered, and, so far as could be observed, had regained her normal mental state.

Dr. R. F. Weir congratulated Dr. Gallaudet on the success of these two cases. He referred to a recent article by Dr. Agnew, in which were reported about ten cases of brain abscess which had occurred in Philadelphia, eight of them being of traumatic origin, and in only one had success followed an operation. Before reading this article he felt some diffidence about reporting the results of his own operations in this class of cases. Now, however, he felt encouraged to say that he had operated altogether eight times for cerebral suppuration. In four of these cases the cerebral abscess was of traumatic origin. One patient out of two operated upon recovered, the other died.

Aortic Aneurism Treated by Macewen's Method.—Dr. R. F. Weir related a case of this kind. It will be remembered that Macewen had reported three cases of aneurism (two of the aorta, one probably of the subclavian artery) which he had treated by irritation of the walls of the sac by the point of a long needle, and also by leaving the needle-point within the sac twenty four to forty-eight hours, with the idea that the walls of the aneurism might thus be more thoroughly roughened. Macewen's observations had shown that the white thrombus that was de-

posited was greatest where the irritation had been most thoroughly applied.

The case in which Dr. Weir had practised this method was one of aneurism of the ascending portion of the aorta, occurring in St. Luke's Hospital. The aneurismal tumor had produced a bulging of the sternum in the region of the second rib. The above-described method of treatment was applied three times, at intervals of five to seven days. On only one occasion he left the needle in, then for three hours. He then went away for the summer, and instructed the patient to submit to a further treatment at the hands of another surgeon, should no benefit follow. This he failed to do, and about two months afterward the tumor ruptured and caused death.

At the autopsy there was no other clot present than the post-mortem clot. The case, therefore, had given negative results.

Dr. J. D. Bryant had made use of Macewen's method on a patient who had a large aneurism of the external iliac. The patient was subjected to two or three treatments, two needles on two occasions being left in the sac for twenty-four hours. Within a week after the second sitting the bruit had entirely disappeared, and never afterward returned. Within a week the tumor began to increase in density and the extensive pulsations peculiar to aneurismal growths disappeared, but the sac had grown in size, and he had not yet made up his mind to repeat the treatment again.

A Case of Sacral Hysterectomy.—Dr. Kammerer read a paper and reported a case. (See p. 207).

Dr. Lange said the same rules mentioned in the paper had guided him in the cases in which he had resorted to sacral hysterectomy, the entire number being three, two of them being of cancerous nature, the other a multilocular interligamentous tumor of the right ovary and extensive syphilitic disease of the rectum. In all the result had been favorable, and he had been struck with the ready access which the method gave to the pelvic floor. It was a great aid in enabling one to distinguish the ureters and other parts, and to apply ligatures, etc. The whole operation became one simply of shelling out the diseased parts and tying the vessels, as one would do in disease of quite accessible parts of the body. He thought that to apply an iodoform dressing to such a large surface would be dangerous. He had seen in other cases disagreeable complications from iodoform absorption. One of his cancer cases had been operated upon two years before, and, as far as he could determine, there had been no recurrence of the disease. The other patient, operated upon a year ago for cancer, had not been seen since she left the hospital.

Dr. Boldt thought there could be no question of the ready access which this operation gave to the pelvic contents, but the two points deserving of special consideration were whether the method did not enhance the immediate dangers, and whether in the class of cases in which it was considered specially applicable, the disease was not so far advanced that it must fail to lengthen life to any notable extent.

Dr. A. F. Currier thought there might be cases calling for the Kraske operation in removal of the uterus, but it was his opinion that the number must be very small. He would supplement it by the actual cautery.

Dr. Edebohls had resorted to this method in one case of cancer of the rectum and vagina. He would draw the line as between this operation and vaginal hysterectomy aided by an abdominal incision at the posterior cul-de-sac. What lay posterior to the cul-de-sac might best be removed by Kraske's operation, while what lay anterior thereto might be removed by the vagina, or laparotomy, or the two combined.

Dr. Kammerer, in closing, took exception to the statement made by Dr. Boldt, that cancerous uteri which could not be removed through the vagina should not be operated upon, because the extent of the disease was such that an early return might confidently be expected. He thought statistics of the Kraske method might, when sufficient time should have elapsed, give other proof.

Therapeutic Hints.

The Treatment of Tapeworm. — We have received several communications relative to the best means for the expulsion of tapeworm, of which the following is a summary. Dr. W. H. Stroup, of Spencer, O., regards chloroform as the best remedy. He prescribes half a drachm in some bland vehicle, followed in half an hour by—

℞. Ol. tiglii ..... gtt. iv.
Ol. ricini,
Glycerine, ... āā ʒ iv.
Aq. destill..... ..... ad. ℥ xvi.
M. Sig.: Two teaspoonfuls every three hours until the worm is expelled.

Most of the writers prefer pomegranates, prepared by boiling four ounces of the bark of the root for half an hour in a pint of water, strain, and drink in the morning, fasting, following it two hours later with two ounces of castor-oil. Another method is to take one half ounce of Epsom salts at bedtime; in the morning no food or drink, but five grains of calomel, followed in ten minutes by four eight fluid ounces of decoction of pomegranate. If the worm is partially expelled copious enemata of salt water should be given. Nausea is relieved by lemon-juice.

Sore Throat.—A gargle of hot claret often affords much relief in cases of acute catarrhal pharyngitis. When the inflammation is rheumatic in character, extract of phytolacca (poke-root), in doses of two to four grains, has been recommended. In the same condition a spray of the following is useful:

℞. Morphinæ .... gr. iv.
Ac. carbolici,
Ac. tannici.....āā ʒ ss.
Glycerini,
Aquæ dest.....āā ℥ iv.
M. Sig.: Use as a spray in the throat, about a teaspoonful at a time.

Insomnia of Alcoholism.—Krafft Ebing speaks very highly of methylol as a hypnotic in this condition. It is employed hypodermically in doses of fifteen minims of a ten per cent. aqueous solution, from one to three times in the twenty-four hours.

Tinea Versicolor.—The following has been used with good effect as an application in tinea versicolor:

℞. Sodii hyposulphitis..... ℥ ss.
Glycerini..... ℥ ij.
Aquæ .....q.s. ad ℥ vi.
M. Sig.: For external use.

Deafness.—In deafness resulting from dry catarrh of the middle ear, Dr. C. Miot has seen good results from the instillation of liquid vaseline. He has never seen this method produce new growths of the tympanum, as is feared by some authorities.—*Gazzetta degli Ospitali*, No. 39, 1891.

Tonsillitis.—Much relief is said to be often obtained by a gargle containing chloral, according to the following formula:

℞. Chloralis..... gr. xv.
Glycerini,
Aquæ.....āā ℥ jss.
M. Sig.: For use as a gargle.

Rodent Ulcer.—A twenty-five per cent. ointment of resorcin in vaseline is recommended in the treatment of this affection.

Hiccough. — Ewald recommends pilocarpine in the treatment of obstinate singultus.

Ichthyol in Erysipelas.—Dr. Julius Fessler, of Munich, claims to have had excellent results in the treatment of erysipelas by means of ichthyol internally and externally employed. It is, he says, inimical to the life of the streptococcus, thereby curing the disease in a few days.

Dermatol and Iodoform.—Dr. Gläser holds (*Centralblatt für Chirurgie*, No. 40, 1891) that dermatol is not in any sense a substitute for iodoform, as it diminishes secretion while the latter excites it. He thinks dermatol may be profitably employed in the case of aseptic (operative) wounds, infected wounds being best dressed with iodoform.

Acetate of Lead in Pneumonia.—M. Marquez claims to have had great success in the treatment of pneumonia by means of acetate of lead. The remedy is, he thinks, particularly efficacious in cases in which there is a tubercular tendency.

Dandruff.—The following pomade is recommended in the treatment of dandruff:

℞. Acidi salicylici ..... ʒ ss.
Sodii boratis ..... gr. xv.
Bals. peruviani ..... ♏ xxiv.
Ol. anisi ..... ♏ v.
Ol. bergamot ..... ♏ xv.
Vaselini ..... ʒ iij.
M et ft. unguentum.

Toothache.—

℞. Acidi arseniosi,
Cocainæ hydrochl. ..... āā gr. xv.
Mentholi ..... gr. iv.
Glycerini ..... ʒ ij.
M. Sig.: A few drops on a pledget of cotton to be inserted into the cavity of an aching tooth.

Catheterization of the Female Bladder.—Professor Parvin advocates the use of the ordinary male catheter, instead of the female, as by its greater length the bladder can be emptied without soiling the clothes or necessitating any exposure of the patient. It is passed into the bladder just as easily as the other kind.—*College and Clinical Record.*

Treatment of Diphtheria.—Dr. William Titus, of Newark, N. J., has had much success in the treatment of diphtheria by means of the following:

℞. Potassii chloratis ..... ʒ ss.
Tr. cardamomi comp. ..... ʒ ij.
Aq. destillatæ ..... ʒ iij.
M. Sig.: A teaspoonful every half-hour for six doses, then every two hours, in a severe case in a child from six to twelve months of age.

In addition the following spray is used:

℞. Zinci sulph. ..... gr. vj.
Ac. salicyl. ..... gr. xx.
Glycerini,
Aq. destillatæ ..... āā ʒ j.
M. Sig.: A teaspoonful in two tablespoonfuls of hot water to be sprayed by a hand atomizer every two hours, or oftener if necessary.

This mode of treatment, Dr. Titus says, can do no harm in a case of ordinary ulcerated sore throat, and is very efficacious in genuine diphtheria. Since using it he has not lost a case of diphtheria, although before that his results had been no better than the average.

Atropine in Lead Colic.—Dr. F. Rowland Humphreys reports in *The Lancet* for November 21, 1891, a number of cases of lead poisoning treated successfully with sulphate of atropine and iodide of potassium. The author concludes that in lead poisoning atropine in full doses, 1, relieves the colic and the pain in the head in the most rapid manner; 2, it keeps the bowels freely open; 3, it assists in the return of the bodily powers; 4, it assists, directly or indirectly, in the removal of the lead by iodide of potassium.

Diphtheria.—Dr. C. Smith, of Casterton, Victoria, writing in the *Australian Medical Journal*, No. 10, 1891, says that he has had great success in the treatment of diphtheria by continuous inhalation of a mixture of one part each of carbolic acid and oil of eucalyptus in eight parts of turpentine. The patient is confined to the bed and clothes wrung out of this mixture are placed and hung about the head of the bed, so the neighborhood is saturated with the fumes. Care must be taken that the mixture does not touch the face, on account of its irritant properties. Internally stimulants, tincture of digitalis, tincture of belladonna, and aromatic spirit of ammonia are given.

Treatment of Erysipelas.—Dr. Trapetsnikoff has been very successful in the treatment of erysipelas by local applications of a mixture of one part of carbolic acid in fifteen parts of turpentine. Cloths dipped in this mixture are applied to the diseased part, being renewed every hour.—*Russkaya Meditsina*, No. 14, 1891.

Burns.—The following treatment of burns is said to be very beneficial. Blisters are not opened, but are pierced with a silk thread soaked in sublimate solution and left in place. The whole burned area is then spread with a ten per cent. iodoform vaseline, and is covered with gummed paper or silk. The salve should be renewed daily. By this plan pain is relieved at once and cicatricial contraction is rare.—*Western Medical Reporter.*

Local Anæsthesia.—Dr. Struver recommends a spray of the following solution as an efficient local anæsthetic:

℞. Cocainæ hydrochloratis ..... ʒ j.
Antipyrini ..... ʒ iij.
Aq. destillatæ ..... ʒ ij.
M. Sig.: For local use.

Pruritis.—Dr. Brubaker recommends the use of the following preparation for pruritus:

℞. Acidi hydrocyanici diluti ..... f ʒ ij.
Sodii boratis ..... ʒ j.
Aquæ rosæ ..... f ʒ viij.
M. Sig.: Use as a lotion.

—*Medical and Surgical Reporter.*

Phthiriasis Pubis.—Dr. T. R. Riddle writes, in the *Medical Brief*, that one thorough application of softened tallow will effectually kill pediculi pubis, together with the nits. A few hours after using, the sufferer must wash with warm soap-suds and be clean.

Bed-sores.—Dr. Keen says that an excellent treatment for bed-sores is the alternate application of cold and hot poultices. Apply a cold flaxseed poultice in which have been placed small pieces of cracked ice; let this remain for ten minutes, and then apply a hot flaxseed poultice. After two hours apply another cold poultice and then another hot one.—*College and Clinical Record.*

Constipation.—Dr. A. E. Nevins has had good results in chronic constipation from the use of Dover's powder. In such cases, he claims, there is a condition of irritation of the large intestine, which the opium allays, but which is only aggravated by cathartics.

Corns are often cured by means of the following application:

℞. Acidi salicylici ..... ʒ ss.
Ext. cannabis indicæ ..... gr. x.
Collodii flexilis ..... ʒ j.
M. Sig: To be applied to the callous part by means of a brush two or three times a day.

Acid Dyspepsia.—The following often affords relief in cases of persistent sour stomach:

℞. Sodii salicyl. ..... ʒ j.
Spt. vini gall. ..... ʒ ij.
Solve et adde,
Syr. aurant. cort. ..... ʒ j.
Vini albi fort. ..... ʒ iij.
M. Sig.: One tablespoonful before meals.

Scaly Eczema of the Scalp.—

℞. Acidi borici ..... ʒ iij.
Bals. peruviani ..... gtt. xv.
Vaselini ..... ʒ ij.
M. et ft. pomatum. Sig.: For external use.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE INFLUENZA EPIDEMIC—THE COMPARATIVE MORTALITY IN INFLUENZA AND CHOLERA EPIDEMICS—RECENT RESEARCHES IN DIABETES MELLITUS—THE COLLEGE OF SURGEONS AND ITS MEMBERS—DEATHS OF SIR OSCAR CLAYTON AND DR. ALFRED CARPENTER.

LONDON, January 30, 1892.

THE influenza epidemic shows no signs of abating as yet. Last week the number of deaths in London primarily due to it rose to 506, and in 86 cases it was registered as a secondary cause of death; the mortality was, therefore, nearly double that of the previous week. The mortality from other diseases of the respiratory organs also showed a further increase last week—the number of deaths from these diseases registered in London last week being more than double the average. In many of the provincial towns there is a similar increase in the death-rate. There are, however, two sides to the shield, and in view of the fact that many pessimists have lately been declaring that the influenza epidemic is worse than a cholera visitation, it is consoling to refer to the recorded statistics on the subject. From these it appears that in 1849 the number of deaths from cholera in the metropolis was fourteen thousand odd; in 1890 the total number of deaths from influenza in the whole country was only 4,523 (only 614 of these in London). Compared with cholera, influenza must, therefore, clearly take a back seat. The mortality from it at the present moment is undoubtedly phenomenal, but it is not to be expected that it will continue at the present rate for many weeks. A reference to the published returns of the Registrar-General also brings out very clearly the fact that it is no new thing for influenza to prove fatal, for some deaths from it have been registered every year for the last fifty years and more—even in the absence of any special epidemic. The highest recorded mortality was in 1848, when 7,963 persons died from it in England and Wales. In 1849 the deaths fell to 1,618, and since then—with the exception of the years 1851 and 1855, when the deaths rose to 2,152 and 3,568 respectively—the mortality has been steadily declining, until it was rekindled by the three recent epidemics.

At the last meeting of the Royal Medical and Chirurgical Society, Dr. H. J. Tylden read a paper on "Recent Researches in Diabetes Mellitus." He first discussed M. Lépine's work on the glycolytic ferment of the blood. Granting the existence of this ferment in the blood drawn from animals, the question was whether it was a vital phenomenon? There were grounds for supposing that it was, but the point could not be regarded as settled. Was the diminution of this ferment in diabetes the cause of the disease? The objections to this theory were, firstly, that probably all ferments were reduced in wasting diseases, and, secondly, that clinical facts warranted the supposition that diabetes was due not so much to failure of sugar destruction as to increase of sugar production in the system. Dr. Tylden then discussed some recent experiments on the pancreas. Extirpation of the gland was immediately followed by diabetes mellitus. Partial extirpation of the pancreas, injection of the pancreatic duct with irritants, and tying the pancreatic vessels, all failed to produce permanent glycosuria, but led to cirrhosis of the pancreas, and were followed by azoturia, polyuria, and wasting. Was the glycosuria which followed upon complete extirpation of the pancreas a result of such extirpation or of some lesion incidental to the operation? The author thought the latter was more likely to be the case. Passing on to the consideration of the morbid histology of the pancreas, he said that cirrhotic changes had been demonstrated in diabetic pancreases, but before they could be accepted as the cause of the disease, the following questions must be answered: 1. Was the lesion constant in diabetes? It certainly was not, some diabetic pancreases showing no departure from the normal on histological examination. 2. Was the lesion confined to diabetes, or had it wider relations with sundry other diseases? A microscopical examination of some fifty pancreases led to the recognition of at least two forms of cirrhosis—the one coarse and interlobular, often seen in very wasted pancreases; the other, finer and intercellular, in pancreases not necessarily wasted. The latter form was chiefly found in patients with granular kidney. The pancreatic changes might possibly throw light in some cases of chronic Bright's disease upon some of the symptoms of the disease, especially when it was remembered that polyuria and wasting were two of the results of artincial cirrhosis of the pancreas. 3. Assuming the first two points, was there any reason to suppose that cirrhosis of the pancreas would, even if present, provoke glycosuria? So far as was known there was not; experimental evidence went to prove the contrary. As none of the questions could be answered in the affirmative, neither the pancreatic hypothesis of diabetes nor M. Lépine's form of it could be accepted.

Dr. George Harley mentioned that as long ago as 1788 a case in this country was described as pancreatic diabetes by Dr. Thomas Cawley. It was not, however, until the last two years that the researches of experimental pathologists had made manifest the importance of the pancreas in connection with diabetes. Dr. Harley said he considered that diabetes was only a sign of several different conditions, as albuminuria was. If extirpation of the pancreas caused diabetes, he could not understand why ligature of the pancreatic vessels should not produce the same results. Experiments performed abroad on dogs showed that the glycosuria resulting from removal of the pancreas could not be due to the damage to the tissues around the pancreas during operation. He did not agree with Dr. Tylden that Lépine's theory should be rejected.

Dr. Rolleston said he did not think pancreatic changes could primarily cause diabetes for two reasons, viz. (1): Although the pancreatic duct were blocked entirely yet no diabetes need occur, and (2) in some cases of diabetes mellitus the pancreas was found to be quite healthy after death.

Dr. Bradford described Minskowki's experiments, in which, after removing seven eighths of the pancreas, no glycosuria occurred; on removing the remainder in the same animal, glycosuria immediately supervened and remained. In a case in which there was diabetes with ascites, a primary growth was found in the pancreas after death; in another case, that of a fine man who had died of diabetic coma, a pancreas weighing under an ounce was found after death.

Dr. Tylden then replied and said he agreed with Dr. Harley that diabetes should be considered as a symptom rather than as a disease. Though it could not be established that sclerosis of the pancreas was always present in diabetes, yet it would not be fair to conclude that sclerosis never produced diabetes. When he had stated that ligature of the pancreatic vessels did not produce diabetes, though extirpation of the organ did, he was simply mentioning facts, difficult though they might be to understand. He had not rejected Lépine's theory, though he could not at present accept it.

The law's delays are notorious, but after pending for some considerable time the case of Steele *vs.* Savory, involving the right of members of the College of Surgeons to meet in the college building, has been decided. The plaintiffs have lost the case on every point of law raised. After hearing their counsel, the judge dismissed their action with costs without calling upon the defendant's counsel at all. He said, that though to the lay mind there might appear to be something in the case, to the legal mind there was nothing. Under the existing charter members of the college had no rights. It is suggested that an appeal may be lodged and the matter

taken to a higher court. It is also proposed to endeavor to get an act of Parliament passed giving members a share in the government of their college. I heard in conversation yesterday a much more summary remedy suggested for the existing state of things, viz., that all members of the college (nearly every practitioner in England and Wales is a member) should refuse to meet in consultation members of the council of the college until they are admitted to some share in the management of the college. Were this done, no doubt some impression would be produced, to say the least, but there is, of course, no likelihood of any such procedure being adopted. The bulk of the profession in fact take but little interest in medical politics, and of those who do, few would care to take such an extreme course as that indicated above.

The deaths of Sir Oscar Clayton and of Dr. Alfred Carpenter are announced. Sir Oscar Clayton was surgeon in ordinary to both the Prince of Wales and the Duke of Edinburgh, and for many years past enjoyed a large practice among the "upper ten." Dr. Alfred Carpenter was chiefly known as a sanitarian. He was an ardent advocate for sewage farms. He was also an earnest temperance advocate, and for many years held important offices in the British Medical Association.

THE TREATMENT OF GRIP.

To the Editor of the Medical Record.

Sir: You published a note of mine giving a succinct statement of the treatment of grip, in which it was asserted that, as in yellow fever, the use of a mercurial purge was essential at the beginning of the attack. A few grains of calomel were recommended to be associated with rhubarb, magnesia, and ipecacuanha, which prevented the necessity of a subsequent dose of oil or salts, and that this invariably broke the force of the disease. To diminish the accompanying fever a fever mixture was advised composed of the sweet spirits of nitre, acetate of potash, spirit of mindererus, with a few drops of tincture of aconite to each dose. Wine and quinine, in tonic doses, were also advised to be given early in the disease on account of the prostration which ensues. If cough becomes troublesome, on account of the engorgement of the lungs, and broncho pneumonia is threatened, syrup of senega or wine of antimony is added, with the application of mustard poultices, turpentine, etc.

Phenacetine, phospho- or bromo-caffeine, which also diminish fever, or other such agents, are required to relieve the pain and nervous disturbance which often accompany the attacks; but these will all be diminished when the purgative produces a medicinal effect.

As the great majority of cases of this disease, on its two visitations, recover as ordinarily managed, it would be presumptuous in me to suggest a method; yet, as many in every city, including some of the most prominent of our citizens, die, I am induced again to urge the importance of the practice cited above, with the hope that it will be fully tested. During the present prevalence of the disease, as before, I have never visited anyone more than four days.

An initial mercurial purge is seldom amiss in the beginning of most diseases ushered in by fever and its usual attendant, costiveness, and the physician has frequently to regret its omission. Essential in yellow fever, I believe that it is equally so in grip, which, though less fatal, is an analogous affection. Quinine also is beneficial in both diseases.

Respectfully,

F. Peyre Porcher, M.D.

Charleston, S. C.

Arms and Legs.—A dealer in artificial limbs says that an arm will last a lifetime if properly cared for, but that after five or six years a leg gives way to the weight and strain, and has to be renewed.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 13, 1892.

	Cases.	Deaths.
Typhus fever	69	0
Typhoid fever	7	6
Scarlet fever	213	30
Cerebro-spinal meningitis	1	3
Measles	176	9
Diphtheria	121	27
Small-pox	7	1
Varicella	18	0
Pertussis	0	4
Erysipelas	3	0
Leprosy	0	0
Mumps	0	0

Public Letters of Approvement.—The proprietors of a newly-discovered mineral water on the continent of Europe have been sending around circulars in the style of "English as She is Spoke," containing among others the following "letters of approvement:"

"It gives me great pleasure to inform you that I tried your famous mineral water on my own person and attained the most remarkable results by using it against the severe gout from which I suffered for years. Now, after having taken it for some time, I can assure you that I enjoy already a great recovery. I found also the water acting very successfully in cases of catarrh of the urinal bladder."

"In reply to your inquiry of the 7th inst., I gladly inform you that the mineral water, which has been prescribed to me by Professor M. Benedikt, M.D., of Vienna, gave eminent proves of its efficacy, against the gout and complaints of the urinal bladder from which I suffered (already after the use of only two doz. of bottles), so that I can say that it highly surpasses every other medicament which I used before. I communicate to you this very favourable result with great pleasure and out of full convincement."

"In reply to your kind lines of the 30th of past month, I am glad to inform you that after having been drinking the water during several weeks, the chronic rheumatism as well as the catarrh of the stomach and intestines seem to be entirely elevated. In consequence of the above said, I can give but the highest testimonial to your mineral water, which you may make use off and publish as you find best."

Vital Statistics of New York City.—The population of this city on July 1, 1891, according to the estimate of the Board of Health, was 1,680,796; that on July 1, 1890, 1,631,232. The number of marriages reported in 1891 was 15,764, as against 14,992 in 1890. The number of births was 46,804, as against 39,250 reported in 1890; of deaths, 43,634, 18,225 being of children under five years of age, the number in 1890 having been 40,230. The death-rate of New York was 25.96 in 1891; in 1890 it was 24.66. The principal causes of death were: Pneumonia, 5,817; consumption, 5,160; diarrhœal diseases, 3,585; Bright's disease, 2,503; heart diseases, 2,287; violence, 1,957; bronchitis, 1,834; diphtheria, 1,363; scarlet fever, 1,221; influenza, 858. Three cases of leprosy were reported; 201 unknown dead were removed to the Morgue, and of these, 92 were subsequently identified; 132 people were reported to the police as missing, but all except 8 were found; 192 persons were arrested for attempted suicide.

Quinine Pills.—A young physician in St. Louis had his faith in quinine seriously disturbed the other day, until he discovered that the three-grain sugar-coated pills he had been taking every half-hour were recently prepared compound cathartic pills.

RECURRENCE OF CARCINOMA OF THE BREAST.

BY FREDERIC S. DENNIS, M.D.,

NEW YORK.

IN a study of the cases of recurrent carcinoma of the breast, only those will be considered in which a thorough microscopical examination of the tumor has been made. All other cases will be excluded as worthless, because a large number of benign as well as malignant tumors of the breast have been grouped under the general class of carcinoma. For these reasons, as well as from the absence of a scientific diagnosis of the many different tumors affecting the breast, our knowledge of the recurrence of carcinoma in this organ is vague and untrustworthy. An attempt will be made to collect cases of recurrent carcinoma, utilizing only those, however, about which an authoritative statement can be made.

The points at issue in this paper are not the relative frequency of carcinoma of the breast, or the proportion in which this disease exists in the sexes, or the conditions under which this neoplasm primarily develops, or the etiology of the growth. In other words, all the various subjects connected with carcinoma of the breast and collateral with it are not included in our discussion to-day. The title of our paper restricts us to one of the multifarious subjects incident to this disease. Possibly many of us may live to see the day when the bacteriological origin of carcinoma will be established, and it is to be hoped that this great discovery will be accompanied by an infallible remedy.

The length of time that a patient may enjoy immunity from this disease after removal of the breast is a problem of overwhelming interest not only to the sufferer but also to the surgeon.

The necessity of an investigation of carcinoma of the breast can be estimated when it is considered that in England alone there are seven thousand deaths annually from carcinoma, and that there are thirty thousand patients suffering at all times in that country from this affection, of which number a large proportion involve the breast. When it is considered that fifty per cent. of the cases of carcinoma of the breast die within three years, and that one-third die within two years, and that of all the tumors affecting the breast eighty per cent. consist of carcinoma, some idea can be formed of the paramount importance of our theme to-day.

The mere fact that carcinoma causes more deaths in the United States in one year than the sum-total of deaths due to erysipelas, tetanus, hydrophobia, lightning, typhlitis, gunshot wounds, joint disease, together with other well-known surgical affections, conveys at once an idea of the wide dimensions of our subject. When we learn that carcinoma causes nearly half as many deaths in one year in the United States as are caused by accidents and injuries of all kinds and descriptions, the importance of our subject is imperatively forced upon us.

For example, in the United States, in one year, there were over thirteen thousand deaths from carcinoma, of which there were twice as many deaths among females as among males. There are over fourteen thousand people in the United States dying each year from carcinoma. There were one thousand three hundred and eighty seven cases of death from carcinoma of the breast alone in this country during the year 1880.

In order to facilitate the discussion of the subject of recurrence of carcinoma of the breast, it is necessary to collect the entire group of cases, and then to deduct those cases from the whole number in which there has been a recurrence. This will furnish us with an approximate estimate of the number of cases in which a return of carcinoma occurs. I have carefully collected cases supplied by the different writers upon carcinoma of the breast, and the result of my work demonstrates the fact that for our purpose a fairly uniform agreement is found as to the relative frequency of return of carcinoma of the breast after surgical interference. The cases of recurrence amount to about seventy-five per cent. of those collected. I have not included my own cases in this list, because I shall take them up subsequently as a separate class, and subject each case to a critical analysis in the light of the clinical history of the patient and the anatomical character of the tumor.

To-day we have nothing to do with the twenty-five per cent. ending in permanent recovery. The fact that one-fourth of the cases never recur, points logically to the conclusion that in the other three-fourths of the cases there is either some defect in the operative technique, or there is an unreasonable delay in arriving at a positive diagnosis, or there is a great diversity in the histological formation of the carcinoma.

It is to an inquiry into the causes of recurrence in the seventy-five per cent. of the cases of carcinoma of the breast following excision of the gland that attention is now directed.

Early and complete removal of the growth relieves the local disease; but the operation does not remove the predisposition or susceptibility or the capability for the recurrence of the disease. It is possible that the capability is limited to a certain extent, but to what extent no one can judge from the study of the life-history of the growth.

One of the most striking illustrations of this fact occurred in the case of a lady who was a patient of Dr. William Pierson, of Orange, N. J. This patient had a carcinoma of the breast removed in 1855, by Dr. Hosack, and the tumor was examined by the late Professor Alonzo Clark, whose knowledge of the technique of the microscope no one would question. Over a third of a century after the removal of the breast, the patient suffered from epithelioma of the rectum, from which disease she died. This is a valuable case for reference, because the microscopical examination was made at the time of the operation, and at a period in the history of medicine when the microscope had not been employed to any extent for such purposes.

I have used the three years' limit as a standard of time representing a permanent cure, because all writers upon malignant disease accept this period of time for the purpose of establishing some fixed rules in regard to the recurrence of malignant disease. I am well aware that carcinoma of the breast returns even when a patient has enjoyed an immunity for over three years. These cases are, however, rare, as they amount to scarcely two per cent. at present, and in order to establish some views in regard to the curability of carcinoma of the breast, it is obvious that some fixed period must be adopted from which as a basis to argue. The case of Dr. Pierson il-

lustrates the fact that for our purpose three years' limit answers as well as twenty-five years.

The recurrence of carcinoma of the breast is influenced, *first*, by the period of time from the appearance of the growth to the date of the operation. I have searched very carefully through the literature of the subject to ascertain, if possible, to what extent the duration of the disease before operation influenced the question of recurrence. Statistics furnish us with no accurate data upon this point. In a study of my own cases bearing upon this subject I have found that in all the cases in group "A." which class represents a permanent cure for three years or more, that the tumors were removed on an average of six months from the date of their first recognition in the breast. It is also an interesting clinical fact that, in nearly all the cases of permanent cure, the axillary glands were not invaded, or at least there was no microscopical proof of an invasion.

In all probability, within six months from the date of the first appearance of the induration in the breast in the cases belonging to group "A," the axillary glands were not infected; at all events the microscopical examination of the glands failed to show any changes. That it is possible for the glands to become infected within this period of time is well established. In other words, the earlier the disease can be detected, the better the prognosis as regards any recurrence, and that in a large majority of the cases the disease can be diagnosticated at a time before glandular infection has taken place; and that, if the tumor can be removed within six months from its incipiency, and the axillary glands and fatty tissues be dissected out, and likewise the pectoral fascia, the peri-mammary fat and para-mammary areolar tissue, the prognosis will yield brilliant results not heretofore realized.

The recurrence of carcinoma of the breast is influenced, *second*, by the extent to which infiltration has taken place by any one or all of the three well-recognized ways of dissemination. When the tumor has existed long enough to show evidence of glandular enlargement, or integumentary infiltration, or metastatic deposit, the disease has been present for some time. If the breast and its adjacent structures are removed with the axillary glands and fatty tissue in the axilla, there is still a prospect of success; but if metastatic deposits have occurred in the distant visceral organs there is hardly a tangible hope for recovery.

In regard to the first two ways of infection, if the area is circumscribed the radical operation may be successful; but if the case had become infected by the third way of dissemination, there is no opportunity offered by any surgical operation to save the patient. If, on the other hand, the infection has spread by the third way, which is by metastasis, there is no hope for a cure. It is a clinical fact worthy of attention, that of the cases in which secondary infection from the breast has occurred, nearly ninety per cent. of them invade the axilla, or, in other words, the disease has disseminated in nearly every case by a way that is amenable to treatment by surgical operation, if taken in time. It is also a clinical fact of a startling character that, in cases where metastases have occurred, nearly fifty per cent. involve the lung or pleura; and it can be demonstrated that in the majority of cases the axillary involvement antedates the lung and pleura infection by several months, which points logically to an important fact, that excision of the axillary glands, with the fat in the axilla, is an imperative step in the operative technique with a view to avoid recurrence of the growth after removal. In one case in group "B," a most extensive and dangerous dissection was necessary, and this patient has as yet no evidence of return. The glands deep in the axilla and those glands beneath the clavicle were all involved.

Surgical interference can prevent recurrence because in ninety per cent. of the cases the return of the disease can be combated, or even be prevented, by removal of the axillary glands and fatty tissue in addition to the complete removal of the breast.

The recurrence of carcinoma of the breast is influenced, *third*, by the radical character of the operation itself.

No Procrustean rule can be laid down, in regard to the extent or character of the operation for the removal of carcinoma of the breast, which would meet the exigencies in every case. A radical operation in one case would be an unjustifiable one in another case. For example, in one patient upon whom I operated it was necessary, besides removing the breast and all its subjacent tissue, and the axillary glands and fat, the pectoral fascia, and the pectoral muscle, to excise the ribs, the removal of which exposes to view the pleural cavity. The ribs were involved in the carcinomatous infiltration, and were thin and eroded through the malignant ulcerative process. This is the first case I can find where the ribs were involved, and where in the course of the operation it became necessary to excise them.

The radical character of this operation would be no index to guide the surgeon in another case, and consequently a radical operation must be performed with certain limitations suited to the special case. There is, however, a standard operation which is none too severe to meet the necessary conditions in every case. The uniform classical operation should include the entire breast gland, all the fatty areolar connective tissue in the vicinity, the integument over the circumscribed area of the tumor and as much more as is necessary, leaving out of consideration altogether the question of flaps to cover the wound, and finally, the pectoral fascia.

I am aware that surgeons will dissent from this severe method of operating just described, on the ground that they can refer to cases where a less serious operation had been performed and no return of the disease followed.

The question of mortality of the operation itself is one of importance, for it is obviously of no avail to remove completely a carcinoma of the breast and enucleate the axillary glands, and tear out the axillary loose fatty tissue, if the patient's life is to be sacrificed in the performance of the operation itself. Let us for a moment investigate this problem, for its solution will throw a flood of light upon the question of recurrence of the disease after operation. After a careful study of the published mortality of the operation, I am convinced that it is the result of this investigation that has made surgeons too conservative. I am aware that the death-rate of the operation is very high, and I cannot account for this excessive mortality. For example, a reference to the published reports made by surgeons reveals the fact that the mortality of amputation of the breast, including both the complete and incomplete operations, was, in Gross's cases, about ten per cent.; in Oldekop's cases, nine per cent.; in Sir Joseph Lister's cases, reported by Mr. Watson Cheyne, about eight per cent.; in Butlin's cases, seven per cent.; in Professor Billroth's clinic, about twenty-three per cent.; in Professor Fischer's clinic, twenty per cent.; in Professor Esmarch's clinic, about ten per cent.; in Professor Küster's clinic, about fourteen per cent. In another list of operations, published by Billroth, the mortality is about fifteen per cent. In a still later list of sixty-eight cases performed by Billroth, there is a death-rate of about six per cent. In my own list of cases of amputation of the breast the death-rate was 1.4 per cent. This is the lowest death-rate that has as yet ever been reported. If the one case of death which was due to continuous bleeding in a patient suffering from hæmophilia be excluded, as it can be with propriety, there is no mortality whatever connected with the operation in my series of seventy-one cases of amputation of the breast. I may add that in my list of seventy-one cases I have endeavored to perform the complete operation.

Before finishing this important part of our subject I cannot refrain from entering a strong protest against Mr. Butlin's views in regard to partial amputations of the breast in cases of carcinoma of the gland. I have been

deeply and profoundly impressed with a study of his book on malignant disease, but I cannot indorse his opinions in regard to incomplete operations upon the breast for carcinoma. I am a strong advocate of always removing, in every case to which there is no exception, the entire breast, with the pectoral fascia and the lymphatic glands, as the minimum operation in the most insignificant scirrhus.

The recurrences of the disease in my cases are much less frequent, and the mortality of the operation only 1.4 per cent., which is not more than would attend an amputation of the finger in pre-antiseptic days. In fact, there was no mortality if the case of hæmophilia be eliminated, since it had no special bearing on this operation.

The last reason that I would adduce to strengthen the argument that the operations should be more radical in order to prevent recurrences, is the report of Küster, who submitted to careful microscopical analysis the glands removed in 117 cases of carcinoma of the breast, and in only 2 cases out of the 117 did he fail to find unmistakable evidences of carcinomatous infiltration. No sounder argument could be advanced than one based upon this report, and it is thus evident that not only the breast must be removed, but also the axillary glands, in order to minimize the dangers of recurrence of the disease.

The radical operation removes cancerous cells that form the foci for recurrences. These cancer-cells may be found outside the limits of the breast gland, lodged in the adjacent mammary region, whence they have been carried by the lymphatic current. I have several times found cancerous masses upon and in and under the pectoral fascia, as well as in the neighboring muscles. These masses were examined microscopically and found to contain cancer-cells. Mere removal of the breast is inadequate to reach the entire disease. In order to secure immunity from the disease in every case, it is necessary to adopt a radical operation as routine treatment in all cases. In a most valuable paper by Heidenhain, presented at the meeting of the German Congress of Surgeons in Berlin, 1889, he pointed out the fact that the ligaments of the breast are often surrounded by projections of the parenchyma of the gland, and contain cancer-cells. This is true in regard to the so-named ligaments of Sir Astley Cooper, as well as those which are retro mammary, and which bind the breast to the fascia. I have even found cancer-cells in the pectoral muscle, the adhesion of which to the posterior surface of the gland indicates the certain presence of cancerous emboli in the lymphatics of that muscle.

Gross was entirely right, some years ago, when he strongly urged the complete removal of the breast as a *sine qua non* to prevent recurrence. Mr. John Chiene even goes further than this, and takes a flap from the arm to cover the wound. The operation, in order to be radical, must be an extensive one.

The recurrence of carcinoma of the breast is influenced, *fourth*, by the histological character of the carcinoma itself. This cause of recurrence of carcinoma of the breast has received little, if any, attention by surgical writers. There has always been a general impression that the atrophic scirrhus, for example, was less malignant than the medullary carcinoma. The reasons for arriving at this conclusion have never been investigated from a purely histological and clinical point of view. I shall endeavor to demonstrate by a complete microscopical examination of my own cases, taken in connection with the clinical history extending over a period of three years, that the histological character of the tumor itself influences more than any other cause the recurrence of carcinoma of the breast. I shall also strive to prove that a reliable prognosis can be made from an examination of the nature of the histological elements which form the neoplasm. I have carefully prepared the clinical histories in each case, and then submitted each tumor for a complete microscopical examination. The result is that the tumors which show structures departing but slightly from the normal correspond in every case with the group of cases the clinical history of which is favorable, because no return of the carcinoma has occurred in any case belonging to that group. The tumors that showed a great departure from the normal structure corresponded to the unfavorable clinical histories. In other words, the microscopical report of the tumors corresponded precisely to the clinical histories. The more typical the structure, the better the prognosis; the more atypical the structure, the more unfavorable the prognosis. Arranging all the cases in four groups, and comparing the microscopical examination with the clinical histories, the recurrence and the non recurrence of the disease in each case corresponded exactly.

The result of the histological examination, when compared with the clinical histories, in this series of cases, demonstrates that the more embryonic the structure of the tumor, the greater the liability of recurrence.

The history of epithelioma of the lip, as compared with epithelioma of the breast, forcibly illustrates this law. The reason is very apparent, as Mr. Heneage Gibbes has demonstrated when he shows by microscopical examination that the carcinomatous cells lie in contact with the stroma. It is inferred that by amœboid movement these cells pass into the interfascicular lymph-spaces, from whence the lymphatic capillaries carry the cells into the nearest gland. This explains the frequency of recurrence of carcinoma in the pectoral and axillary glands, and the metastases later on in the lungs and pleura. That recurrence takes place first in the neighboring glands is shown by the fact that, in 128 autopsies of patients dying from carcinoma of the breast, ninety per cent. of the cases had return of the disease in the axilla, and of the entire number forty-five per cent. involved the lung and pleura, and nearly forty-three per cent. involved the liver. Primary carcinoma of the axilla, of the lung, of the pleura, or of the liver, is so rare that it may be considered among the medical and surgical curiosities, whereas secondary carcinoma is extremely common.

The recurrence of carcinoma of the breast is influenced, *fifth*, by the appearance simultaneously of carcinoma in both breasts. Fortunately this condition only exists in about five per cent. of the cases.

The appearance of double carcinoma makes the prospect of recurrence greater, owing to the more extensive infiltration. In double carcinoma of the breast the secondary deposits are most likely to occur. These infiltrations and metastases are found very early in the history of the case.

The recurrence of carcinoma of the breast is influenced, *sixth*, by the personal factors of the individual, such as age, sex, marriage, fecundity, sterility, traumatism, heredity, menstruation, locality, race, nativity, etc.

In order to draw any conclusions from the personal factors as to recurrence of carcinoma after removal, it must be assumed that any laws which operate to develop carcinoma primarily have not entirely lost their influence in bringing about a recurrence. The capability is not always removed with the local infection. This view is in perfect harmony with the constitutional theory of carcinoma, and can be easily reconciled to the local theory of cancer—a theory in which I am a firm believer.

That carcinoma may be present in the body in more than one place at the same time, and a common cause independent of auto-infection underlying the malady, has been proven in many cases.

Age has an indirect influence upon recurrence or metastases, since it has a marked effect upon the primary growth. It has been demonstrated that eighty-two per cent. of the cases of primary carcinoma of the breast develop after the fortieth year, and that the average is the forty-eighth year. The tendency to the development of carcinoma of the breast is declining after sixty years; the conditions are also unfavorable for recurrence or me-

tastases. It is an interesting fact that the maximum frequency of carcinoma appears ten years earlier in the female. In other words, there seems to be less malignancy in carcinoma affecting the breast in the early stages of obsolescence of the gland than when the gland has fully completed its degenerative changes. Age, therefore, has marked influence in regard to recurrence, for the older the patient is, within certain limitations, the more malignant the carcinoma appears. The nearer the gland is to a healthy functional activity, the less likely is it to assume malignancy.

Sex has an indirect influence upon the recurrence of carcinoma of the breast, since the disease exists in the male in the proportion of one to every one hundred cases in the female. In my list there was only one case in the male sex, since metastases occur in over six per cent. of the cases of breast carcinoma in those organs in the female that are absent in the male, and metastases are seldom, if ever, found in the corresponding organs in the male. I have observed six additional cases of carcinoma of the breast in the male besides the one already mentioned.

Marriage, without doubt, has a direct influence upon primary carcinoma of the breast, since eighty per cent. of the cases are found among married women. This would leave twenty per cent. to represent the unmarried class. The same law, therefore, which operates to cause carcinoma in one breast incident to marriage, will not altogether lose its force in causing a further extension of the disease in the opposite breast, or by dissemination by the first way of infection in the cicatricial tissue. In my list of permanent cures all the patients, except one, were married.

Fecundity seems to affect the frequency of carcinoma of the breast. Mr. Thomas Bryant, in his excellent book upon "Carcinoma of the Breast," has pointed out the interesting clinical facts that seventy-four per cent. of the women were prolific, while only twenty-six per cent. were sterile.

In my list I find that all the married patients had children, except one. In other words, there was only one patient who was married and who was sterile. These patients, however, were not prolific to an extreme degree, as in Mr. Bryant's cases. The average was three children, instead of ten or more as in Mr Bryant's cases.

Traumatism has a direct influence on the development of carcinoma of the breast in about thirteen per cent. of the cases, according to some writers. In the male, traumatism has been assigned as the cause in nearly fifty per cent. I am certain that if friction, irritation, and mechanical stretching of the scar after removal of the breast can be classed under the head of traumatism, that a very large proportion of the cases of recurrences are due to this cause, the prevention of which is possible in many cases.

If wearing unsuitable corsets can in any way be assigned as a cause to develop carcinoma in a woman in whom a predisposition exists, certainly this would be a most potent factor in the etiology of recurrence. A soft pad should always be worn in contact with cicatricial tissue following excision of the breast, in order to obviate one of the causes of recurrence of carcinoma.

The recurrence of the disease in the scar can be largely prevented by the exercise of care in instructing the patient how to treat the tissues thus formed after the removal of the breast. Some idea of the importance of mechanically protecting the scar, after removal of the breast, can be formed by the knowledge of the clinical facts, that recurrence of carcinoma of the breast occurs in "nearly every instance"—according to Butlin—"under or close to the scar." Von Winiwarter has also demonstrated that in Billroth's cases the recurrences originated in the scar-tissues This idea impressed the late renowned Langenbeck to such an extent that I remembered his having suggested in his clinic the dressing of the wound with the patient's arm placed at right angles to the trunk, in order that the scar-tissue might form without contraction. Excision of an irritable scar will certainly remove a potent cause of recurrence of carcinoma after excision of the breast.

Mastitis accounts for nearly thirty per cent. of cases of carcinoma of the gland. If this irritation is sufficient to develop the disease in the breast of a patient in whom a predisposition exists, a comparable irritation, like a low grade of inflammation in young connective tissue, certainly would have a corresponding influence.

In one patient upon whom I have operated for carcinoma of the breast—in the case of the wife of a well-known physician—traumatism in the form of a fall where the patient struck her breast upon the edge of the bed, a carcinoma was developed in one gland, while the other breast, which had been previously the seat of mastitis leading to abscess-formation, escaped. In other words, in this case traumatism seemed to have been a more potent factor in causing carcinoma in a breast than a mastitis; for the breast exposed to traumatism developed carcinoma, while the breast which was the former seat of an abscess has shown no tendency to give rise to the disease, although the evidences of an old abscess are still apparent in the remaining breast. I have recently seen another case illustrating the rule that traumatism seems a more potent factor than mastitis in causing carcinoma of the breast.

In my list of cases studied with reference to this point, I find that mastitis is quite common; but I also find that in the most malignant group traumatism stands out as a most prominent etiological factor—more so than mastitis.

Heredity also may be assigned as a factor in developing secondary growth in twelve per cent. of the cases. A study of the cases of carcinoma of the breast will demonstrate the fact that a larger number of recurrences and metastases will be found in those cases of carcinoma of the breast in which an hereditary influence is present.

The locality of carcinoma has a marked influence upon the recurrence after its removal. Carcinoma is prevalent in the New England States, and on the Southern Pacific Coast, in the central part of Michigan, and the southern part of Wisconsin. Dr. Billings has pointed out the interesting fact that in "any given locality a large proportion of cancer indicates that the locality is healthful and a long-settled one, and has a large proportion of inhabitants of an advanced age," and that the higher the state of civilization, the greater the number of cases of carcinoma.

Race has a marked effect upon the development of carcinoma of the breast, and hence the law operates in regard to the recurrence, or metastases, or multiplicity of growths. There is a marked difference between the white and colored race, as regards carcinoma. For example, among the whites the proportion of deaths from carcinoma per 100,000 is about twenty per cent., and for the colored race about five per cent.

Carcinoma, irrespective of age, is more than twice as prevalent among the whites than the blacks. It is also a disease rarely found among the Indians, or the uncivilized inhabitants of the islands of the Pacific.

Nativity seems also to influence the development of carcinoma, and also the recurrence. The Germans are more liable to carcinoma than the Irish, and the Irish more than the native whites. Native-born Americans are less liable to the disease, with its recurrences or its metastases, than the Irish or the Germans.

The conclusion to which I have arrived from a careful study of these cases, in regard to the question of recurrence of carcinoma of the breast after removal, will be considered. In the first place, I have complete notes of one hundred and five cases of tumors of the female breast which have come under my personal care. I have in complete notes of many other unpublished cases that I have treated in addition to the one hundred and five; but, as the histories are so defective as regards the union

of the clinical history with the microscopical examination, I shall exclude them altogether in the summary.

In the one hundred and five cases of tumors of the breast never before published, there are thirty-four cases which must be eliminated, because among the one hundred and five cases there are specimens of adeno-fibromata, sarcomata, cystic tumors, galactoceles, syphilitic mastitis, and other varieties which do not belong to carcinoma. There are also a few cases of carcinoma of the breast in which the disease had extended so far as to render any operative interference unjustifiable, and also there are a few cases in which the patients themselves declined any operation. Deducting these cases from the total number, there are left seventy-one cases of amputation of the breast.

The cases of carcinoma of the breast I have arranged into four separate groups: In Group A are found cases in which the patients are permanently cured, or where the patients have reached the three years' standard of time without any evidences of return. In Group B are found cases in which the patients have not yet quite reached the three years' limit of time, and therefore, according to the standard mentioned, cannot be said to be permanently cured. In Group C are found cases in which the patients have been operated upon, and in whom a recurrence of the disease, in the scar or in the axillary glands, has taken place, followed by death. In Group D are found cases in which the patients have been operated upon, and in whom metastases have occurred in visceral organs, followed by death.

I have before me on the table the history of each case and a microscopical slide of the tumor, with a written opinion from one of the three well-known microscopists. I have also appended the names of the physicians who were present at each operation. The tumors are preserved in alcohol and are in my private collection of pathological specimens in the museum of the Carnegie Laboratory.

In regard to the operative cases, I have performed amputation of the breast seventy-one times, and in nearly every case opened the axilla and removed the glands. In this series of seventy-one consecutive cases one patient died from the immediate effects of the operation. This patient suffered from hæmophilia and bled to death, in spite of everything that could be done to prevent the constant hemorrhage. Including this case of death, the mortality of the operation is 1.4 per cent; excluding it, there is an unbroken series of seventy consecutive cases without a death. In addition to the reduction of the mortality from as high as twenty-three per cent., recorded by Billroth, to a cipher, it can be also said that there was no case of pyæmia, septicæmia, erysipelas, or abscess.

Besides the question of mortality, the question of permanent cures effected by the operation is one to which great interest is attached.

In the list of seventy one cases of amputation of the breast, a number must be eliminated in estimating the percentage of permanent cures. This is necessary, because some of the tumors were of other varieties of malignant disease, and while this would not affect the question of mortality in reference to the operation of amputation of the breast, it would affect materially the question of cures beyond three years in carcinoma.

In the thirty-three cases of pure carcinoma of the breast in which the clinical histories and the microscopical examinations are complete, there were eight permanent cures of over three years' limit of time. Deducting the two cases in which the histories are unknown, the result is over twenty-five per cent. of permanent cures beyond the three years' limit of time.

It is fair to assume that in Group B, where the patients have not quite reached the three years' limit, that there will be some who in a very short time can be classed in Group A of permanent cures. This would bring the percentage of cures up to nearly thirty per cent., if not over thirty per cent.

Thus a study of my seventy-one consecutive cases demonstrates the fact that the mortality has been reduced from twenty-three per cent., as published by Billroth, to 1.4 per cent., or, if the case of hæmophilia be excluded, from twenty-three per cent. to zero.

The percentage of permanent cures from fifteen per cent., which is the best result, and published by Mr. Banks, to nearly double or thirty per cent.

Finally, I believe this great reduction in the mortality of the operation will have a marked effect upon the radical character of the operation in the future. As a natural sequence the percentage of permanent cures will be increased. I feel justified, in view of these facts, to prophesy that, with early and radical operations, the recurrence of carcinoma of the breast after removal of the gland will be, comparatively speaking, of less frequent occurrence. I feel confident that with the early recognition of the disease, and with complete operation, together with the improved methods in the technique, that amputation of the breast for carcinoma of that gland will yield results more brilliant and startling than the most sanguine surgeon could imagine.

The high death-rate in the operation has been largely due to causes which aseptic surgery can prevent, the frequent recurrences to causes due to delayed and incomplete operations. In some cases the returns are due to the character of the growth.

A new era is about to dawn in regard to this dark night of surgery, and patients who have hitherto been doomed to a certain death, can be in the future rescued by the application of fixed and well-established principles which have been either never understood or overlooked. Surgery will thus prolong life and mitigate suffering. It will even save life in cases of carcinoma of the breast, a disease which in the past has blighted so many homes, but in the future will be deprived of its malign influence through the advances made by scientific surgery.

ON THE USE OF CREOSOTE IN THE TREATMENT OF PULMONARY PHTHISIS.[1]

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

Among the numerous remedies which have been praised during the last few years in the treatment of pulmonary phthisis none seems to be so useful as creosote. Moreover, none has acquired in its favor a larger number of competent and careful clinicians.

The information I have obtained as to its importance is not merely that taken from printed reports of cases, nor simply from hospital histories—which as regards the therapeutics of chronic disease are of necessity unreliable—but it is also the information afforded by the results which I have reached with patients in private practice. These latter cases are especially valuable because I have been able to watch them carefully in almost every particular, and because I have continued my observations of some of them during many months, or even years. Besides knowing the conditions which surrounded them I have been able at times to regulate them. For this reason complications have been infrequent and my conclusions are less open to criticism than they otherwise would be. Judged fairly in comparison with other drugs I have come to regard creosote as the most valuable medicinal agent we have at the present time for the treatment of pulmonary tuberculosis.

On many occasions, also, I have questioned my medical brethren closely, and I have been much gratified to find that almost invariably they speak of creosote in terms of like praise.

Despite the fact, therefore, that there is possibly nothing new to offer you, and although the literature of creosote may be more or less familiar, I believe a discussion

[1] Read before the Section of General Medicine, at the New York Academy of Medicine, November 17, 1891.

of the subject by the members of the Section of General Medicine of the Academy will be interesting and profitable. The reports of your proceedings are read with great interest, I believe, by nearly all American physicians of repute. I am sure, therefore, that whatever is thought of creosote by the members of this Society will forcibly influence the thought and action of medical men throughout the United States.

Recognizing this fact, I have requested your Secretary to accord me permission to open the discussion with a short statement of what I consider to be the essential points of the creosote treatment of pulmonary phthisis.

Some of you are aware that I presented a paper on "Creosote as a Remedy in Phthisis Pulmonalis" to the Association of American Physicians at their meeting held in Washington, September, 1888. This paper, unfortunately, was not read at the meeting owing to lack of time. Later it was published in the "Transactions of the Association," with the appended cases, and also in the January number of the *American Journal of the Medical Sciences* for 1889, without the cases. In this paper I showed how I was led to use creosote among the first in this country, how my faith in its virtues gradually increased, and upon what basis this faith was supported. I concluded from my own observations and those of numerous clinicians, mainly in Europe, that the curative effects of creosote in the treatment of phthisis pulmonalis are very notable and merit recognition. Indeed, I was almost inclined to be enthusiastic about the drug, had my zeal not been wisely tempered with the knowledge of what a long, obstinate, and dread disease we have to do with. To day I have just the same confidence in the utility of creosote that I had more than three years ago, and the faith which is in me has increased rather than diminished. With an additional and broader field of experience the results obtained have not become more doubtful. On the contrary, they have been confirmed and strengthened. What are these results?

First, as regards the general symptoms. They are nearly all benefited by the use of creosote. Some are not, however, benefited immediately, or always in the same measure. Again, there are some patients in whom, I confess, the benefit is slowly obtained and with certain drawbacks. There are very few, however, who do not experience marked relief in one or more ways from the use of creosote.

Cough is very soon much diminished in frequency and severity. This is, of course, more often true of phthisis at its first stage than it is of phthisis pulmonalis at its second and third stages. Nevertheless, even in the advanced stages of lung involvement, where cavities are already present, cough is decidedly ameliorated after some months of continuous treatment. The diminution of the cough is doubtless due to the local effects on lung-tissue produced by the remedy. What these are I will state later on.

Expectoration is diminished in quantity and changed in quality. Not infrequently, at the first stage, it disappears altogether after a few months of treatment. In the advanced stages it lessens in amount one-half or two-thirds on many occasions, and from yellow or green it may become grayish, or frothy and colorless.

Nutrition is notably aided by the use of creosote. This is shown by increase of weight, which may be of two to three pounds only, or in rare cases, of ten to twenty pounds. With increase of weight there is augmented strength and activity. The mind is less depressed and sluggish, the body is more easily incited to in door or out-door exertion of any kind. Hence all the internal viscera—the liver, kidneys, bowels—not to speak of the lungs themselves, are functionally put in better form. Appetite for food returns, and patients who previous to treatment took very little nutriment are apt to eat with relish and pleasure at their regular meals. The digestive processes are certainly strengthened, and bowels which had been costive move with much regularity. The breathing becomes deeper, fuller, and more satisfactory. The patients appreciate and state it. The spirometer, under the doctor's eye, indicates it with unerring certainty. This latter affirmation is not a borrowed opinion, but the expression of my own observation. Night-sweats often disappear while the treatment is carried on, and those who have previously suffered from them are astonished that they no longer appear. The temperature record is often favorably influenced by the treatment. In many cases, without making use of any drug except creosote, I have seen the fever allayed and at least be temporarily absent. The kidneys, as a rule, remain in normal condition, and the secretion of urine is sufficient, and very rarely shows any signs of morbid change.

In regard to the bacilli in the sputa, I am sure in several instances that they have entirely disappeared. This statement is taken from that of men who made the microscopic examinations, and who are not likely to be deceived. In some instances expectoration stopped and there was really nothing to examine for bacilli. Besides, as the other symptoms were all so much improved, it was reasonable to infer that the bacilli were gone, or if present, were in very small number. Even presuming that they existed in the lungs, although not raised, there is, and may properly be, in the minds of some of us, a query as to their importance and precise significance as regards prognosis.

Locally, I am confident that the signs have often been ameliorated. In a few exceptional cases in which I have had frequent and long-continued opportunities of watching, the diseased processes have unquestionably become entirely quiescent. Many times moist râles limited to the apices have become fewer. Occasionally they have disappeared entirely. Under these circumstances I have been uncertain whether or not areas of softening at the apices had become cicatrized. In view of other attendant conditions and symptoms, which were at the same time much improved, the more favorable judgment seems also the more probable one. In making this statement I am erring, perhaps, on the side of too great conservatism, rather than on that of over-confidence. The breathing, after several months of continuous medication, has often become less harsh and high pitched, and the area of consolidation distinctly smaller. I base this affirmation upon the evidences afforded by auscultation and percussion. In such instances not only was the breathing softer and more vesicular, but the note obtained by percussion had become less dull and the wooden return more limited in extent. In certain instances, when cavities were surely present at the apices, I have been convinced, after a while, that the areas in which loss of tissue was obvious had contracted in a marked degree, and accompanying this contraction all physical evidences of local disease were somewhat favorably modified. Whether or no the contraction of cavities be due to the increased formation of fibrous tissue, I am not prepared absolutely to decide. This opinion, however, which is intelligent, appears to me, also, highly probable.

Many of my patients before taking the creosote treatment had made a thorough trial of other approved methods. The rule was that they had already taken, unsuccessfully, cod-liver oil, the hypophosphites, malt, arsenic, and strychnine. Now and then I have known of or met a patient who had been placed in Williams's Pneumatic Cabinet, or had been subjected to Weigert's plan of hot-air inhalation, or had been fed with the stomach-tube after Debove's plan, or received injections per rectum with sulphuretted hydrogen. In some of these, when the treatment later with creosote had been continued a sufficient length of time to test it, a conviction was established in their minds that they had finally taken hold of what was most serviceable to them. Even now, when "tuberculin"[1] or "parataloid" injections seem to hold

[1] Or, indeed, the latest *trouvaille*, viz., tuberculicidin, or modified tuberculin.

under their sway the minds of a few of our best clinicians, I remark with more than curiosity that creosote is given internally, though injections of the former are at the same time being made. This appears to me very faulty from a rational point of view. If there be any real benefit resulting from the Koch fluid, or its improved modification, let us find out as soon as we can just what and how much this benefit is. How can we do this unless we abstain from other modifying treatment of more or less value.

In regard to corroborative cases of my statements I would refer those who wish to consult them to my original paper. With respect to other and newer cases I will gladly read, at the end of this communication, if the Society desires it, from the notes on one or more of those persons who have latterly been under my care. But I will not in this place destroy the unity of my reading by interpolating them.

What are the drawbacks, what the contra-indications in the use of creosote? Does it ever work harmful results? The objections to the use of creosote are few, and if any occur, they are usually obviated by a little judgment and good sense. Occasionally the stomach becomes intolerant. This is shown either by headache, inappetence, and a sluggish feeling in the performance of usual duties; or there is slight pain or uneasiness in the region of the stomach, evidently brought on by the action of creosote. These ill-effects are frequently occasioned by a too rapid increase of the dose, by a faulty method of administration, or by some evident personal idiosyncrasy; or, indeed, the true explanation is simply that there is an irritative or weak stomachal condition connected with the presence of tubercular deposit in the lungs and dependent on catarrhal gastritis, or a possible atrophy of the gastric tubules. The remedy of this state is not far to seek. Diminish the dose of the remedy for a time, or in extreme cases interrupt its use for a while, and resume prescribing it in small and slowly increasing doses, and more frequently repeated, only after a period of complete rest from taking it. If diarrhœa be occasioned by its use, the same rules apply, or, indeed, an appropriate opiate may be added in small amount to each dose with good effect, so far as toleration is concerned.

In a late number of the *American Journal of the Medical Sciences* the reporter for the *Journal*, in commenting upon Dr. William H. Flint's able article, seems to fear the injurious effect of creosote on the kidneys. In only a few instances have I had my fears aroused in this direction, although my attention has long been awakened to its rare occurrence. Usually the ordinary tests for creosote do not show its presence in the urine. It has been found there, however, and it is therefore conceivable that it may irritate the kidneys at times in a pronounced manner. I do not believe, after careful watching, that this will often take place, unless large and frequent doses of the drug be given. It is true that under these circumstances I have recognized a passing albuminuria, which disappeared when the amount of creosote taken by the patient was diminished. I think it is wisdom, in view of such facts, to be on one's guard and to examine the urine carefully every few days, at least, when the patient is taking large amounts of creosote.

Is it a contra-indication to the use of creosote when renal disease already exists? In reply, I would say that under these circumstances I have given creosote and have observed no ill effects from its use, although it is true I have not been willing to increase the dose beyond six or eight minims in the twenty-four hours. In so doing I believe I have acted prudently and wisely.

In regard to hæmoptysis is there any reason to believe that the use of creosote occasions hæmoptysis, or makes patients more liable to it? According to Dujardin-Beaumetz, creosote in appreciable doses, and while it is eliminated from the body by way of the respiratory organs, congests the bronchial mucous membrane and thus promotes the occurrence of pulmonary hemorrhage. According to him the drug is strongly contra-indicated whenever hemorrhage actually occurs. Nothing in my experience thus far tends to corroborate this view. It seems to me prudent, however, to recognize the possibility of what Beaumetz affirms, and for this reason to interrupt the use of creosote during the time there is hæmoptysis, or an evidently imminent tendency to it.

In regard to the creosote itself, it is all important to make use of the genuine wood creosote, and particularly of the creosote obtained from the beech-wood, and to employ no other. Even now, and although attention has been directed to the regrettable fact by me, much so-called creosote that is dispensed is nothing but impure carbolic acid. Consequently evil, not to say poisonous, results are not infrequently obtained when we had a right to anticipate great amelioration, if not cure, supposing the pure drug had been taken. To prove the great importance of my statement, and to avoid all misapprehension, I refer my readers to an article by Dr. G. W. Dagwait, entitled "Impure Creosote the Cause of Failure in the Treatment of Pulmonary Tuberculosis," and published in *The Occidental Medical Times* for June, 1890. As to the preparation which is most eligible, I still believe the formula which I borrowed from Jaccoud, and which he apparently took from Bouchard and Gimbert, to be most generally useful. Still there are cases when the solution of creosote in whiskey with glycerine apparently agrees less well with the stomach than an emulsion with cod-liver-oil and the hypophosphites, or a mixture with wild cherry and gum, with or without a small quantity of morphine. The emulsion is now used preferably at St. Luke's Hospital, and I believe the formula for it was taken from Dr. W. H. Flint's article in the *New York Medical Journal*, July, 1890. The combination with wild cherry seems rational, and is employed by an eminent practitioner of a neighboring city.

With respect to the quantity of creosote to be used daily, opinions differ. My own judgment is to give small quantities at a dose, from a half to one minim, as a rule, and to increase its frequency gradually from three to four times daily to every two hours, if the stomach does not become intolerant. Of course there are instances in which I have deviated from this rule, and have carried the amount of creosote, with obvious advantages for a while, to twenty or twenty-five drops in twenty-four hours.[1] But I have very rarely been able to hold my patients at this dose for any length of time without some intercurrent objectionable symptoms arising which made me desist from increasing the dose, and usually made me diminish the quantity of the drug, or stop its use altogether for several days. Stomachal or intestinal disturbances, headache and general malaise, slight albuminuria, or hæmoptysis, have been symptoms which have thus guided my action.

I am well aware that my experience is not that of other observers. I know, indeed, the views of Sommerbrodt and Gutmann and Beaumetz and others, but I have not been convinced by their statements. I explain my lack of belief in them, as applied to my patients, because I have found that the American stomach will not, for one reason or another, bear as much creosote as is given across the water. Besides, I do not believe that the theory which upholds the use of creosote mainly on account of its obvious anti-microbic action is the one that is most satisfactory in explaining its effects in favorable cases, and therefore it is that I have never sought to make the blood-serum in a living individual, by reason of the quantity of creosote carried in it, capable of killing the active bacilli. This being the case I have not sought ways of reaching the lungs other than by the stomach, as the rectum or the subcutaneous tissue. The first way open to us, viz., the rectum, cannot but be a temporary make-

[1] In one case under my care at present, as much as sixty-four minims of creosote has been taken daily by the mouth without any unpleasant or injurious effects. Such a case, however, is exceptional, and must not be regarded as a standard ordinarily.

shift and presents no advantages over stomachal medication, except in a few instances when the stomach having become intolerant we do not wish to interrupt the medication altogether. As to the use of subcutaneous injections of creosote in sterilized olive-oil, I can only say that I have not been able to recognize its advantages except in regard to the larger quantity of creosote that it is possible to administer in this manner. As I do not regard this as desirable, especially when the drug should be administered for many months, not to say years, I am very sceptical in regard to its permanent and decided value. Still, I am forced frankly to add that this is the way toward which modern research inclines, not only for this drug but for several others now being used in the curative treatment of pulmonary phthisis (*i.e.*, gold, tuberculin, etc.). When compared as to its value with inhalations of hot air, of fluorhydric acid, of aniline (and also its internal use), of injections of gold, goat's milk, etc., of "lavage and gavage," where does creosote stand? Evidently it is superior to them all, if the concurrence of good medical thought and experience be the judge, and if the duration of the time during which it has held the favor of well-balanced, careful, and judicious observers be the test of any treatment.

What do we see to-day in the hospitals of New York—at the New York Hospital, at St. Luke's, Bellevue, the Roosevelt, Mount Sinai, Charity? Creosote is given by both visiting physicians and house staff with undiminished faith and in increasing quantities. I have yet to meet a practitioner who has carefully made use of it who has not some faith in its curative virtues. I have assuredly met a large number who feel we have in creosote to-day the best and most available medicinal remedy known to physicians in the treatment of pulmonary phthisis.

Is creosote only to be given by the mouth? Is there no other channel by which it can be introduced into the economy with resulting advantages? In my opinion frequent and long continued inhalations of creosote are extremely useful and should almost invariably be regarded as a very important adjunct of the internal administration. These inhalations when properly and systematically employed will unquestionably at times occasion positive and remarkably good results. In some instances of very obstinate and distressing cough they diminish its intensity and frequency very much. I have known this to be true when the internal administration had failed to do it in such an evident manner, or to the same degree, when unaided with this additional curative means. Repeated inspections of the laryngeal mucous membrane while treatment was continued have proved to me beyond a question that the larynx is at times very favorably modified by these inhalations. I have seen the mucous membrane which was extremely inflamed and thickened become almost of normal coloration, and I have sometimes thought that œdema and ulceration were modified advantageously. I know, even now, of no more practical method of continuous inhalation than the use of the perforated zinc inhaler, which in the hands of myself and others has proved so very useful. The ease with which inhalations are thus conducted, and the fact that few, if any, evil effects can result even from their injudicious use are strong arguments in their favor. Theoretical and even experimental objections have little importance, to my mind, in opposition with what I have so often observed in the treatment of patients. These may now be counted by the hundreds, and are always, of course, steadily increasing in numbers.

Latterly, in such appropriate cases of simple catarrhal inflammation as I have been able to treat in my office, I have made use of vapor inhalations from Beseler's globe inhaler. This method I have found more satisfactory during the past winter, as I have controlled a sufficient amount of air-pressure, thanks to the Edison electric plant, to make the inhaler work satisfactorily. I am of the opinion, as stated elsewhere, that these inhalations may prove to be of great remedial service whenever they are followed up assiduously and regularly. I only gave up their employment for a time on account of the practical difficulties in the way of obtaining benefit from them. Hereafter I hope these will be sufficiently removed for me to recur to them frequently. In tubercular phthisis such inhalations must be helpful in addition to those which are taken with the perforated zinc inhaler, mainly for the reason that the vapor is formed under considerable pressure and enters the lungs in greater volume and with greater power of penetration than when the air which is drawn through the sponge of the ordinary inhaler enters the respiratory passages. I have employed many different substances in inhalation by means of the zinc inhaler, but for phthisis pulmonalis I know of none so satisfactory as creosote. It must be combined with alcohol in the proportion of one part to eight, or it would be too irritating for the throat and could not be used continuously. When I say continuously I do not mean that the inhalation of creosote should be used all the time, but I do mean that little by little the duration of the inhalation and the frequency should be increased. Finally, the inhaler can often be worn hours at a time with comfort and advantage; but this end must not be reached too soon, and if such an attempt be made, in many instances failure results and the patient complains of irritation of the throat and beginning of the respiratory tract.

When the inhaler is worn by degrees a longer period of time it often affords comfort and relief. The amount of inhaling fluid poured on the sponge of the inhaler is usually about fifteen or twenty drops. More than this amount does not work so well. Always begin inhaling by wearing the inhaler a short time, and little by little increase the duration from a few minutes—say ten or fifteen—to half an hour, an hour, or more. The proportion of creosote to alcohol in the inhaling fluid is, as I have stated, ordinarily one drachm to the ounce. Of course this amount could be increased or diminished, but as a fact this proportion is most satisfactory. The worst results which can occur from inconsiderate use of the inhaler are to produce throat irritation at times, or to burn the lips slightly, if the sponge attached to it is brought in contact with them. There are some other details which I could mention in regard to the creosote treatment, but I refrain from doing so because I do not wish to monopolize too much time, and because I am well aware that most of what I have read is familiar to many who are listening. What I desire is to hear a very interesting and important topic properly discussed, and to have an excellent treatment receive due consideration as to its merits from prominent and able men of this Section. If I have praised the creosote treatment too much, I wish to be told so.

If I have merely voiced the prevailing convictions of those present, I would like to hear them from their own lips. In any event nothing but good can come, in my belief, to a vast number of unfortunate sufferers from establishing the creosote treatment of pulmonary phthisis on a reasonable and assured basis.

The following note from my late house physician, Dr. L. F. Bishop, seems to me of considerable importance in connection with my paper:

"St. Luke's Hospital,
"Fifty-fourth Street and Fifth Avenue,
"New York, November 18, 1891.

"My Dear Dr. Robinson: Over fifty patients of the House of Rest for Consumptives have taken the enteric pills of creosote of Dr. William H. Flint, in doses of from six to fifteen daily. The pills have been, almost without exception, well borne. A few cases of diarrhœa, which were at first attributed to the pills, were probably due to other causes. We began to use the pills about September 1st, and now use them to the exclusion of the creosote mixtures.

"L. F. Bishop."

The following is a letter received by me from Dr. E. L. Trudeau, of Saranac Lake, N. Y. :

"November 17, 1891.

"DEAR DR. ROBINSON: In regard to my personal experience with creosote in the treatment of pulmonary phthisis, I can only say that after watching the results of its exhibition for three or four years I have not lost confidence in its usefulness. Its value, in my opinion, is due not to any direct germicidal influence which it may exert on the tubercle bacillus, but to its efficacy in correcting fermentations of the digestive tract, so common in this disease, thereby improving appetite, digestion, and nutrition, and also to the beneficial influence it exerts on the secondary, inflammatory, and suppurative processes in the lung, which accompany the deposit of tubercle to a greater or less extent, and constitute so formidable an element of pulmonary phthisis. Thus far it has been truthfully said, the tubercle bacillus 'bears cheerfully' a degree of germicidal medication which may prove injurious to its host, and there is no proof that creosote differs in this respect from other germicides. This view seems to derive support from experiments made by others and by myself upon tubercular animals, in which the tubercular process is seen to be entirely uninfluenced by the largest doses of creosote given daily hypodermically. Clinically, however, the drug does seem to increase appetite, to improve digestion and nutrition, and to diminish cough and expectoration.

"In prescribing it, therefore, cases in which the digestive tract is at fault, or in which the inflammatory and suppurative processes are most prominent, should be selected rather than those in which the physical and rational signs point to a purely tubercular process.

"The best method of administering it is usually by the stomach, in capsules containing two drops of pure creosote to four grains of subcarbonate of bismuth, one to three capsules being given after each meal, according to the tolerance of the individual. In some cases, however, it seems to disorder the stomach, and cannot be exhibited in sufficient quantities to be effective. In these cases I have found the administration per rectum to leave the stomach free, and answer every other indication. Much larger doses can be given in this way, twenty to thirty-five drops of pure creosote may be mixed, according to the French method, with one to two ounces of almond oil, and beaten up gradually with the yolk of one or two eggs, subsequently thinned a little by the addition of a few drops of water, and injected on retiring, two or three times a week.

"The patient tastes the drug within a few minutes of its administration, and its odor can be detected before long in the breath.

"Creosote seems to be withstanding the test of time, and it may be said to be perhaps more useful than any other drug in combating a disease, the drug treatment of which has ever proved most unsatisfactory.

"E. L. TRUDEAU."

The following is a letter from Dr. W. C. Glasgow :

"ST. LOUIS, MO., September 30, 1891.

"MY DEAR DR. ROBINSON: In reply to your inquiries about my experience with creosote in pulmonary disease, I would say, after using the American, German, and French creosote, I find that the English (Morson's B. Creosote) is the best creosote for internal use. In many cases where druggists have substituted other makes of creosote for the English, I have detected the substitution by the bad effect. Creosote is like whiskey, the older it is, the better it is tolerated.

"To creosote a patient, it is necessary to give it in the largest doses which a patient can take without producing disturbing symptoms. This I call the point of tolerance. Individuals vary in the amount of creosote they can take, or in the point of tolerance. For some a dose of five drops is the maximum; others can take twenty to thirty, and one case is now taking thirty-seven drops three times a day. As a vehicle, I give preference to milk; next this, California port wine.

"I usually commence with two drops, dissolved in two drachms of whiskey, and this is added to a glass of milk; this dose is given after meals twice daily. Every third day the individual dose is increased by two drops, and this is continued until the point of tolerance is ascertained; when gastric distress is evident, the remedy is discontinued for two days, and on the third day it is recommenced with a dose two drops less than the one which produced the disturbance. When milk does not agree with the patient, I use California port wine and dilute freely with water. With these forms of vehicle I find the patient can take creosote for several months continuously without distress or disgust. The glycerine mixtures used for a length of time here have not proved as acceptable to the patient.

"In addition, I use the creosote inhalations made by adding creosote to hot water This I much prefer to the dry inhalation, also the creosote ointment with vaseline as a base. In miliary tuberculosis and generally disseminated tuberculosis I have seen no benefit from its use. In fibroid phthisis its effects have not been marked. In phthisis I have found great benefit. In the first stage it almost always improves the condition, removes symptoms, and increases appetite, weight, and strength. In the second stage there is often great improvement, with changes in the symptoms and physical signs which show the tendency toward an arrest or chronicity of the disease. In the third stage equally satisfactory results are not so frequently obtained, but even here the change of the physical signs is seen, showing the tendency to arrest; the fluid gurgling becomes dryer, and in many cases the symptoms, such as fever, sweats, and cough, are greatly improved. The expectoration is very frequently diminished or checked.

"The best and most marked effect of creosote is seen in the chronic stage of cellular infiltration of the lungs, a condition which I described in the March No., 1889, *American Journal of the Medical Sciences*, and which has been lately noticed by Finkler, of Bonn, in his last work on 'Infectious Pneumonias.' These cases are often mistaken for tubercular cases, and to our great astonishment we find an unfavorable prognosis not sustained.

"I believe that we have in creosote a remedy which defertilizes the lung tissue and renders it an unfavorable soil for the growth and development of micro organisms. It is also an excellent expectorant. Combined with other measures to promote nutrition, it seems to me to be the best remedy which we have up to the present time to favor an arrest of many forms of tubercular disease.

"Yours truly,

"W. C. GLASGOW."

Milk a Microbe Killer.—Dr. Freudenreich has found by experiments that the cholera bacillus, if put into milk drawn fresh from the cow, dies in an hour, and in five hours if put into fresh goat's milk. The bacillus of typhoid fever takes twenty-four hours to die in cow's milk, and five hours in goat's milk. Other microbes suffer a like fate in varying periods. But he has also found that milk maintained for an hour at a temperature of 131° F., loses its power to kill microbes—a statement which is of interest in face of the common teaching which makes the purification of milk depend upon its being boiled. Again, the bactericidal properties of milk become weaker the older it gets, for cow's milk after four days, and goat's milk after five days, cease to have any effect upon micro-organisms.—*Annales de Micrographie.*

Inebriate Physicians.—The *Medical Press* proposes that physicians who become intoxicated while engaged in visiting patients shall be suspended from the right to practise for a certain period of time, on conviction of an offence "infamous in a professional respect."

EMBOLISM OF THE PULMONARY ARTERY IN CHILDBED.[1]

By EDWARD L. PARTRIDGE, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF OBSTETRICS IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; VISITING PHYSICIAN TO THE NEW YORK HOSPITAL, AND TO THE NURSERY AND CHILD'S HOSPITAL; ASSISTANT VISITING PHYSICIAN TO THE SLOANE MATERNITY HOSPITAL.

In connection with the puerperal state, the occurrence of embolism of the pulmonary artery is such a sudden and terrible complication—often occurring when the patient is regarded as well on in a favorable convalescence, and affording time and opportunity for little more than a recognition of the appalling calamity—that one is justified in subjecting an individual case to scrutiny. As the causes of the accident are made, more and more, a matter of common understanding, we may hope to prevent, sometimes at least, the occurrence, as we are well-nigh powerless to give aid after the attack is established.

It would seem that the subject ought not to be considered from the obstetric stand-point only, for the study of general pathology affords lessons and illustrations of interest and importance, which should elucidate the subject.

In December, 1887, I attended a patient whose history was the following: The confinement was the second, delivery taking place at term. After her first confinement, which required the forceps for a complete inertia uteri in the second stage, she was left with a uterus larger than normal, and a relaxed condition of the muscular structures of the pelvic floor. This condition was not the result of cervical or perineal injury, and I mention it to show the physical type which she represented. This was further illustrated by general flabbiness of the muscles and disinclination to effort—evidence of poor circulation being manifested by fulness of superficial veins of the neck and hands, and a weak, easily accelerated heart action. She had no abnormal heart-sounds. In this second labor, weak uterine action was present, though the child was born without instrumental aid, after a tardy second stage. The placenta was delivered after considerable stimulation of the uterus. There was such marked disposition to subsequent relaxation of the uterus, that I continued sitting by the bedside for three hours with the hand upon the uterus. This attention obviated any excessive loss of blood, and when the patient was left, she had a good pulse, a satisfactory uterine contraction, and no after-pain. During the following night, after-pains came on with considerable severity, and continued, with gradually decreasing discomfort, for thirty-six hours.

No flow beyond normal attended the after-pain and the fundus uteri kept just below the umbilicus. As the pain passed off a good-sized clot was expelled. From this time no more after-pains occurred, and convalescence progressed satisfactorily. The lochia appeared normal, having no odor. Temperature, pulse, and appetite were normal. The uterus diminished in size, though less rapidly than usual.

On the tenth day following labor, when making my call, the nurse reported that the patient had been annoyed by slight odor to the lochia—which at this time were free from blood admixture—and that she desired a vaginal douche. Up to this time no douches had been employed, but when the nurse verified the patient's statement of slight odor on this day, I allowed the douche. Immediately after my call the douche was given, with results which were most alarming. I was immediately sent for, but being out I did not reach her until two hours later. I was told that, connected with the giving of the douche, a hemorrhage had occurred, and from that time she had alarmed those about her by her appearance, and the constant and excited complaint that she was very sick. A most casual examination confirmed this, her own opinion. The pulse was about 120, weak, and difficult to count.

[1] Read at a meeting of the New York Practitioners' Society, January 8, 1892.

As the bed had not been disturbed after the douche—which had been actually interrupted by the supervention of the grave symptoms—I was able to note the quantity and appearance of the blood lost. There were a number of clots which, from their dark color and firmness, must have been in the uterus some time before their discharge. Altogether, these clots could have been held in one hand In addition, there was considerable staining of the bed linen. Vaginal examination showed the cervix open enough to readily admit the finger into the uterine cavity, and as the uterus had not contracted much after the dislodgement of the clots, the cavity was appreciated as amply large to have held them. There was no odor to the clots, and none left on the examining finger. It was evident that hemorrhage did not explain the general condition. My suspicion of embolism of the pulmonary artery, already entertained, was soon confirmed as I continued to observe the patient. A well known consultant, who arrived a little later, hesitated between this diagnosis and that of entrance of air into the circulation. The appalling picture of the next two hours, until death came, could never be forgotten. Until fifteen minutes before death there was, on the part of the patient, the most keen recognition of approaching death. The senses seemed more than usually acute, and the pleading for life was incessant. The consciousness and dread of dying was chiefly the theme, rather than her distress and suffering. The latter, special complaint was for "air," and for relief to her breathing.

The face was pallid, not cyanosed; the pulse rapid, feeble, irregular, and impossible to count for a full minute. The extremities were cold. An examination of the chest was wholly unsatisfactory, any such attempt being too much for the patient to tolerate as seeming to interfere with respiration. The heart-action, though weak, was tumultuous. After unconsciousness, death came so quietly as not to be recognized at once by friends.

No autopsy was obtained.

On reviewing the case, though without the help afforded by post-mortem examination, I should readily reject the view of entrance of air into the circulation as the cause of death, for the following reasons: Ten days after labor the retrograde changes in and about the uterus would have so far advanced as to make it impossible for air to be forced or aspirated into its venous system in any amount, if at all. Cases of sudden death from this cause, as I have seen them reported, occur immediately, or within twenty-four hours, after labor. Had air entered the cavity of the uterus (as it could have done readily by aspiration, even), the open and relaxed cervix in this case would have afforded easy exit for it in event of contraction of the body of the uterus. Schroeder states that air does not spontaneously ascend into veins of the uterus, but must be forced into them by uterine contractions and an obstructed os.

The differentiation between embolism and thrombosis, in the absence of autopsy, cannot be made so readily. The strongest point in favor of embolism in this case lies in the supervention of the signs of obstruction of the pulmonary artery at the moment of the washing out of old clots from the uterine cavity. The mechanical disturbance of the uterine organ by the forcible dislodgement of such clots, which had resisted spontaneous discharge for days, could materially assist in freeing some coagulum situated in a uterine vessel, and facilitate its movement through the ovarian or uterine vein into the ascending cava. In view of a previously normal convalescence, such a coagulum would have been nothing more than one of the number which always close all torn uterine vessels after the discharge of the placenta. Certainly there was no other peripheral thrombosis from which an embolus could have been obtained.

Regarding the etiology of obstruction of the pulmonary artery in childbed, much that is interesting has been written. There seems to be a slight preponderance of these cases in primiparæ.

Some observers—notably Richardson, Playfair, and Barker—have reached the conclusion that, not infrequently, the obstruction is a *thrombosis* of the pulmonary artery. In favor of the spontaneous coagulation in this vessel it is noted that in the latter half of pregnancy there is found a marked increase of fibrin, and of water as well. Also, in many cases, a loss of blood at the time of labor lessens the force of the blood-current, and after hemorrhage the power of coagulation is increased in the blood which remains in the system. After labor, and during involution, in which process almost all the organs of the body participate, the blood is surcharged with the materials of retrograde tissue change. These conditions are the common accompaniment of normal parturition.

Other conditions, at times met with, favorable to thrombosis, are the blood states of rheumatism, of cancer, and of septic infection; less often still, possibly those of cholera, diphtheria, scarlatina, and fevers, especially those of malarial and tropical regions.

Other, equally prominent, writers, by direct statement or by implication, would seem to favor the opinion that, were our investigations thorough enough, we might find that obstruction of the pulmonary artery, following childbirth, was of embolic origin in all cases. We readily find the origin of the embolus from a thrombus of an iliac or femoral vein, discoverable both during life and upon autopsy, in about one half of all cases. In the other class of cases no peripheral thrombosis has been known to exist during life, and none discovered (or at least mentioned as found) in post-mortem examination. In one case reported, which would have gone into this latter class except for very close scrutiny, a thrombus was found in a small hemorrhoidal vein, from which a fatal embolism of the pulmonary artery resulted.

In looking over recorded cases, I do not find that much scrutiny has been bestowed upon the uterine vessels.

In the great majority of the reports mention will be made of the condition of iliac or femoral veins, and nothing said of the ovarian or uterine veins. When allusion has been made to the latter it has been, often, a passing one.

Furthermore, would it not be possible for us to have embolism of the pulmonary artery by the detachment of a thrombus which was small, and perhaps of physiological nature only, and—were post-mortem examination permitted—what should we expect to find other than the absence of the coagulation-plug from the uterine vein?

In other words, would there always be a lesion, readily discoverable, pertaining to the uterus and appendages, when there had been a dislodgement of a thrombus from the ovarian or uterine vein? This question I raise for consideration in connection with the cases reported where no thrombus has been found other than the obstruction in the pulmonary artery, and in regard to which some writers have been satisfied to assume spontaneous coagulation in the pulmonary artery. Winckel calls attention to the frequent association of the invasion of the attack of embolism with bending, straining at stool, violent laughter, lifting, etc. These acts could have no etiological relation to a thrombus of the pulmonary artery, but could favor the detachment of a part of a fibrinous plug from some small peripheral thrombus.

The objection might be raised that the anatomical arrangement of the veins of the broad ligament, in complicated plexuses, would interfere with the direct passage of an embolus from a uterine vein to the ascending cava. Admitting this to be sometimes true, we would have, by the detention of such embolus in a vein of the broad ligament, a nidus for a rapidly-forming thrombus at this situation, which could be the source of the embolus which would find its way into the pulmonary artery.

Charpentier rejects absolutely the theory of spontaneous coagulation through the influence of the blood-state of pregnancy, because of the infrequency of the occurrence.

If we may have spontaneous coagulation of the blood after labor, it may properly be asked why this should always occur in the pulmonary artery. It must be remembered that this is the one situation, in that part of the circulating system containing venous blood, to which emboli derived from parts in and about the uterus could have access. Why do we not see thrombosis of the cerebral sinuses after parturition? Two answers have been made to this question, neither being very satisfactory, in my opinion. One explanation offered has been that the blood reaches its maximum of impurity in the right heart and pulmonary artery, and is in consequence more ready for spontaneous coagulation here than elsewhere. The other theory explains a greater coagulability in this part of the circulatory system, on the ground that the highly coagulable contents of the thoracic duct are poured into the subclavian vein and modify the blood of the pulmonary artery.

Playfair—who is the strongest advocate of the idea of a possible primary thrombosis of the pulmonary artery—believes, from a study of twenty-five cases, that obstruction of this vessel from thrombosis occurs before the nineteenth day after labor, and that obstructions developing after the nineteenth day are due to embolism. He, however, reports a case in full in which embolism of the pulmonary artery occurred eight days after an operation in the rectum, the peripheral thrombus in a vein in this situation being found on post-mortem examination.

Correct conclusions upon this question of primary thrombosis of the pulmonary artery will not depend upon theory and clinical observations alone. Much will be learned through the habitual examination of the fibrinous plug found in this vessel, to ascertain whether it is all recent, or part recent and part old, together with most careful search for peripheral thrombosis.

Regarding diagnosis of obstruction of the pulmonary artery, it may be said that there is rarely a deviation in clinical aspect from that of the case reported. A clearly defined murmur at the orifice of the pulmonary artery may be added in some cases. In one instance reported by Richardson, the patient could lie best with face downward. In one case of Playfair's, the patient could breathe best when perfectly flat.

While the prognosis is extremely grave, cases of recovery have been reported by several observers, and I venture to introduce the report of one, quite typical of this nature, reported by Playfair, who first and chiefly of all writers stated his belief in the possibility of recovery.

A woman on the third day after labor had syncope from fright, followed by sense of oppression at the chest and greatest difficulty in breathing. She improved somewhat until the ninth day, when on walking to her couch the symptoms came back. For the next two weeks or more the patient could not lie down. The least excitement or talking brought on aggravated dyspnœa, which seemed to threaten instant death. She panted and struggled, her chest heaving with short, gasping respirations. She waved people from in front of her, calling for more air. Pulse, 130, very small and feeble; face, deadly pale. The attacks continued to be frequent, brought on by trivial causes. She talked in a suppressed voice, as if with no spare breath. Auscultation showed entrance of air to lungs in every direction, in front and behind. Percussion clear and resonant. No râles. Immediately over the site of the pulmonary artery, there was a distinct, harsh, rasping murmur, confined to a limited space, and not conveyed upward or downward. Heart-sounds were feeble and tumultuous.

For days the patient had great dyspnœa, faintness, and coldness of the extremities, the left hand being colder than the right. She could utter two or three words only at a time. She had little sleep, and could not take the recumbent posture. The heart was tumultuous, and the heart-sounds faint. After about ten days, improvement began. One month after the attack the pulse was 90, breathing was improved, color good, and skin warm. She could walk a little. Six weeks after attack, breathing

was perfectly natural and quiet, and any position could be assumed. Cases of recovery have been reported by Spencer Wells, Wade, and others. Paget reports a case which lived a week. Richardson reports a case living several weeks. In these, the diagnoses were verified by autopsy.

It is probably true that pneumonia of childbed, also, from which we may have recovery, is sometimes of embolic origin.

Regarding treatment, the earlier writers uniformly recommend carbonate of ammonia. Playfair says the main element in such cases is the most rigid rest and nourishing, supporting regimen.

Stimulation, to be judiciously employed, ought certainly to be mild.

Barnes, looking toward the prevention of the accident, advises against massage to a leg recovering from phlegmasia dolens, lest detachment of a portion of the thrombus may take place.

The experience of the case reported by me emphasizes, on new grounds, the importance of such attention to the uterus, at the time of labor, as will prevent, if possible, the formation and retention of coagula in its cavity, and obviate the need of local treatment during the puerperium, by the establishment of normal involution.

CONVULSIVE TIC; ITS NATURE AND TREATMENT.

By GR.EME M. HAMMOND, M.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The term "convulsive tic," applied to the class of cases of which this paper treats, may be somewhat misleading, for the reason that several affections differing from each other, clinically at least, have been generalized under this heading. Thus the term "convulsive tic" in England, and with some authors in America, is almost exclusively used with reference to what is generally known as "facial spasm;" while the terms "habit chorea" and "habit spasm" are employed synonymously to designate that form of mobile spasm which, it seems to me, should more properly be called convulsive tic. Convulsive tic is characterized by brief spasmodic contractions of individual muscles, or groups of muscles, with periods of rest between the spasms varying in duration from a few seconds to several minutes. The muscular movements are usually quickly made and sharply defined, and differ materially from the slower, aimless, and almost continuous muscular contractions of chorea. Sometimes the spasms are limited to one extremity, sometimes to the muscles of the face and head, and again a spasm of the muscles of one part of the body may be almost immediately followed by spasmodic movements in various other regions. The term "habit chorea," first introduced by Weir Mitchell, seems to me to be entirely inappropriate, as the movements of convulsive tic are not in the least like those of chorea. I have in one instance witnessed the two diseases exemplified in the same patient, when the contrast between the two forms of spasm could be readily differentiated. The term "habit spasm" suggested by Gowers, seems to me to be equally inapplicable to this affection, as it implies that habit has something to do with the genesis of the spasms, and as habits are acquired from the repetition of voluntary acts, it would indicate that the individual began by executing the spasms voluntarily, and that afterward they became automatic. Such, however, is not the case. The word "tic" is derived from the French, and signifies a "jerk" or "twitch." Hence it seems to me that the term "convulsive tic" is the most appropriate title for this class of spasmodic disorders, and more accurately describes the most prominent feature of the disease than any of the others.

Convulsive tic usually begins in childhood, and unless it is arrested sometimes continues through adult life. In many other cases the disease, after continuing with greater or less severity for several months or years, gradually diminishes and eventually disappears. Sometimes a distinct neurotic history can be traced in either one or both parents, but in all cases there is probably a strong neurotic tendency on the part of the affected individual

The situation of the spasms and the number of muscles involved varies greatly in different individuals. Sometimes the facial muscles only are affected, the muscles of one side of the face being seized with spasm *en masse*, producing what is known as facial spasm, or one or more muscles may be involved separately or in succession, so that the affected individual is compelled to make a series of facial contortions, sometimes affecting one side of the face, sometimes the other. Sudden, quick jerks of the head in almost any direction are not uncommon, while shrugging of the shoulders, and quick, jerky spasms of the muscles of the arms, legs, and trunk are frequently observed.

Respiratory spasms are not infrequent. There may be sudden expiration or inspiration, accompanied by various laryngeal sounds, such as grunting, sobbing, groaning, barking, wheezing, sniffing, and sighing. The spasms are not at all controllable by the will-power, and are usually intensified by observation and by the excitation of the emotions, particularly those of annoyance and anger. The principal characteristic of the affection is the sudden spasm of muscles from a quiescent state, the transitory nature of the spasm, and the distinct interval of rest before any particular spasm is repeated.

Morbid Anatomy and Pathology.—In considering the question of the pathology of convulsive tic we must necessarily enter very closely on the pathology of all forms of mobile spasm. There are two forms of muscular spasm—the spastic and the mobile—the one characterized by rigidity and contracture, the other by varied forms of contraction and relaxation. Among those diseases in which mobile spasm is a prominent feature are included epilepsy, chorea, athetosis, the various forms of tremor, convulsive tic, and other similar motor disorders. The mobile spasms of these diseases differ from each other very materially in character, so different are they as to be readily distinguishable the one from the other, and yet they are all mobile spasms differing from each other only in degree, and are really the outward expressions of very similar pathological conditions. What the pathological difference is which in one case causes chorea, in another case convulsive tic, and in still another case paralysis agitans, we cannot determine. There must be a difference, for aside from the varied forms of the spasms almost every form requires a different treatment, which should not be the case if the morbid changes were identical in all instances. In some cases no pathological change can be discovered at all. In other cases well-marked organic lesions, such as hemorrhages, cysts, milliary aneurism, tubercular growth, vascular and perivascular disease, and other well-recognized morbid conditions are observed. But this strange feature is recognized, that very similar lesions in different cases are manifested by very dissimilar forms of mobile spasm. For instance, a tubercular growth which invaded both optic thalami in a case reported by Sharkey, produced bilateral tremor, while very similar lesions have been observed by Demange, Gowers, and others, to be followed by athetosis and ataxic movements.

The view is almost universally held that any of the various forms of mobile spasm may result from disease of any part of the motor tract in the brain. This view was first concisely set forth by Demange, who also holds that the variety of movement does not depend upon the seat of the lesion, but rather upon the condition of the motor tract below the lesion.

With these ideas I cannot concur. On several previous occasions I have endeavored to show that lesions of certain parts of the motor tract are invariably followed by spastic spasm and never by mobile spasm. Recent

pathological contributions have only tended to confirm this view. A vast difference exists between the symptoms produced by lesions of the motor or co-ordinating cells on the one hand, and lesions of the conducting motor fibres on the other. Irritation of the latter is invariably followed by spastic spasm. This effect is commonly observed to follow hemorrhages and other lesions involving the motor division of the internal capsule, crus, and pons, and from lesions affecting the motor-conducting fibres in the lateral columns of the spinal cord. I have been unable to find a single recorded case of mobile spasm in which the lesion has been found confined exclusively to the motor-conducting fibres. On the other hand, in every case in which a lesion has been discovered at all, it has been found to implicate either the motor cortex, or some part of the thalamus or striatum, or the cell area of the pons and medulla. Where the motor fibres are coincidently injured with the cell areas referred to, spastic spasm invariably accompanies the mobile spasm. I have therefore been led to conclude, from a study of all the recorded cases I have been able to collect, that all forms of mobile spasm, including convulsive tic, depend upon lesions of the motor cerebral cortex, the thalamus, the striatum, and the cell areas of the pons and medulla. The lesion must be in the nature of an irritation. Destructive lesions result in paralysis, irritative lesions in spasm. In those functional cases of mobile spasm in which recovery occurs either spontaneously or under treatment, the irritation of the nerve-cells depends upon some cause which is capable of being removed, or, in other words, it is not organic. Toxic conditions of the blood; malnutrition of the cells from blood deficient in nutritive qualities; molecular changes in the cells from shock or fright, together with, in many cases, an innate tendency to the development of neuroses, probably constitute the causes of the majority of cases of convulsive tic and other functional mobile spasms. It is very evident, therefore, that mobile spasm cannot be regarded as a condition due to any lesion which is constant either in position or in character.

It seems to me, therefore, from the foregoing, that the view generally held, that mobile spasm is due to a lesion of any part of the motor tract, is erroneous and untenable, and that it can be positively demonstrated that such spasms depend upon irritative lesions of either one of the basal ganglia, the cerebral motor cortex, or the pons and medulla, and that it is frequently impossible, in the present state of our knowledge, to determine with accuracy in which of these areas the lesion is situated.

Treatment.—As I have previously remarked, one of the evidences that a pathological difference exists between the different varieties of mobile spasm consists in the fact that each form has its own particular remedy, which seems to be practically inoperative in other forms of mobile spasm.

Thus arsenic, which is considered by many to be almost a specific against chorea, is almost valueless in the treatment of epilepsy, paralysis agitans, and, in my hands, of convulsive tic, and hyoscine, which is about the only remedy which seems to have a controlling influence on paralysis agitans, is found to be quite useless in the treatment of any other form of mobile spasm. In the treatment of convulsive tic I have secured the best results from the internal administration of conium and atropine. I think the efficacy of these remedies is greatly enhanced by combining them with moderate quantities of bromides. Bromides alone have not proved successful in my hands, nor have I been more successful with arsenic, either hypodermically or *per orem*, and I have on more than one occasion witnessed a decided aggravation of the symptoms after the administration of iron, strychnia, and phosphorus. Perhaps in very mild cases tonics may prove serviceable, but in the severer forms of the disease I have not witnessed the improvement from them which has invariably followed the use of conium or atropine. The latter remedies when properly used will, in the majority of cases, be sufficient to control the manifestations of the disease if it is not due to an organic lesion; but I feel convinced that the recovery of the patient is greatly accelerated by the administration of small quantities of bromides with atropine or conium. In my experience cases have yielded more readily to conium than to atropine. Both of these remedies should be given at first in small doses, and the quantity gradually increased. With the atropine I usually begin with a dose of about the $\frac{1}{100}$ of a grain, and gradually increase it to the $\frac{1}{40}$ of a grain. It is seldom necessary to increase the dose beyond this point. With conium I have used the fluid extract and the alkaloid conine. I have not observed any greater benefit from the use of one than from the other. To derive the best advantages from conium it should be used in increasing doses. I think better results could have been obtained by other observers if this remedy had been pushed to the proper extent. Beginning with an initial dose of five drops of the fluid extract, I increase the dose one or two drops a day until the tic ceases or until the physiological effect of the drug is produced. Sometimes a patient can take from thirty to fifty drops at a dose without experiencing any inconvenience. As soon, however, as the patient begins to complain of weakness, vertigo, and double vision the dose should be reduced to the original quantity and increased as in the first instance. The majority of cases will be relieved by smaller doses than are required to exhibit evidences of toxæmia. The following cases, selected from a number of others, are typical examples of the disease.

Case 1.—Consulted me on September 29, 1891 She was then eight years of age. Her mother stated that the convulsive movements began when the child was three years of age. At first the shoulders and arms were the only parts affected, but gradually the disease extended till at the time of her first visit to me there was hardly a muscle of the body which did not participate at intervals in the almost continuous muscular action. The eyelids and the muscles of the face and of the neck were frequently the seat of spasms, so that sudden facial contortions, accompanied by violent jerking of the head, usually backward and laterally, occurred every few moments. Jerking of the muscles of the arms, legs, and trunk were also frequent and violent. She had been sent to school when she was five years of age, and had always been considered unusually bright and intelligent for her years, but in the past few months she seemed indifferent to her studies, became inattentive, forgetful, and stupid. Her face wore that vacant unintelligent look which is often seen in severe cases of chorea and epilepsy.

The mother was strong-looking and apparently healthy, but had suffered from chorea in childhood and in later life with migraine. The father was healthy in every way so far as I could ascertain. The patient had been treated for chorea by two different physicians at different times, and had taken arsenic in large doses and for a long time, without any apparent relief. The day before I saw her she had reached a dose of twenty-two drops of Fowler's solution three times a day, and it certainly did not seem to me, judging from the severity of the muscular spasms, that the arsenic had exerted any beneficial influence. The mother stated that she could see no improvement from the arsenic.

The child was weak, pale, and badly nourished. There seemed to be a slight tendency to lateral curvature of the spine, but this was probably a simulation, due to weak muscles of the back. There were nausea and vomiting, but this I attributed to the arsenic, and the patient complained of almost continuous headache. The mother stated that the child was restless in her sleep, moaned frequently, and seemed to have unpleasant dreams. The convulsive tic ceased during sleep.

I prescribed bromide of sodium in doses of ten grains three times a day, together with the sulphate of atropia, beginning with an initial dose of $\frac{1}{960}$ of a grain, and gradually increasing it till a maximum dose of $\frac{1}{40}$ of a

grain was reached. For the first few days the toxic effects of the atropine, such as dryness of the throat and dilated pupils, were quite apparent, but these symptoms shortly disappeared and did not return.

The improvement of all the symptoms was gradual but steady. The headache ceased within two days, the nausea in about the same length of time; the sleep became quiet, and seemed to be more refreshing; the appetite returned, and with it the strength of the child increased rapidly. The mental condition improved, and soon the patient was as bright as ever.

The first sign of abatement of the muscular spasms was seen in about a week after treatment began. It was then observed that the patient did not roll the eyes as much as she formerly did. The facial muscles were next affected, then the muscles of the extremities, then the shoulders, and, finally, the muscles of the neck. Shrugging of the shoulders and jerking of the head backward and laterally were observed to occur occasionally for some time after the tic had ceased in all other parts of the body. The patient was last seen on December 11th, a week after treatment had been abandoned. There was no return of the tic.

Case II.—This patient was a lad, thirteen years of age. His father says he developed convulsive tic when he was three years of age. The movements were not confined to any special area then, but occurred in almost all the voluntary muscles. This condition lasted between three and four years, when it disappeared spontaneously. Since then he has had attacks of it every fall. At first these annual attacks were of short duration and yielded readily to tonics, and were limited sometimes to the legs, sometimes to the arms and shoulders, and sometimes to the head and face. Each attack seemed to be more severe, to last longer, and to resist the usual treatment more stubbornly.

The present attack came on in the last part of June, 1891, and affected the muscles of the face and neck. Occasionally there would be spasmodic movements of the shoulders.

His physician, searching for reflex causes, had performed the operation of circumcision; had had his nose burnt out; his tonsils cut; and had had him fitted with glasses for the correction of astigmatism. All of these various operations were necessary and were properly performed, but they apparently exerted no curative influence as no amelioration of the tic was observed. The usual tonics, iron and strychnia, had been given without effect, and arsenic, given in increasing doses, was administered in large quantities, but without diminishing the spasms either in frequency or in severity.

The boy was strong, well developed, and was fond of out door exercise, and indulged in it properly. He was bright, and as attentive to his school duties as boys of his age usually are. No neurotic history of either parent could be obtained. When I first saw him he had attacks of spasmodic closing of both eyes and rolling of the eyeballs, spasm of the angles of the mouth and nose with an accompanying inspiratory sniff, corrugation of the brow, various other facial contortions, and a rapid and violent snap of the head backward or sideways. If he happened to be speaking coincidently with these sudden movements of the head the words were violently jerked out of his mouth. The muscles were quiescent during sleep.

I prescribed for him the same treatment that I gave to Case I., with the exception that the dose of bromide was slightly greater, fifteen grains being given three times a day. No difference was made in the dose of atropia. There was not the slightest improvement for ten days. At the expiration of that time the tic seemed to be slightly better, but not markedly so. The atropine was then discontinued, and the fluid extract of conium was substituted in its place. The initial dose of the conium was five drops three times a day, and this dose was increased one drop daily till a maximum dose of twenty-five drops three times a day was taken. No improvement was observed till a dose of nine drops was reached; then the spasms began to yield rapidly to the treatment, and by the time a dose of sixteen drops was reached not a trace of the tic could be observed. The remedy was continued for several days longer, and was then gradually reduced. There has been no return of the tic.

Case III.—A gentleman, forty-two years of age, consulted me about a year ago. He developed the first symptoms of convulsive tic when he was about eighteen years of age, and the disease has never left him. Some days he is comparatively free from it, other days the spasms follow each other rapidly; as a rule there is a distinct interval of four or five minutes between the attacks. All of the voluntary muscles seem to be implicated, not at the same time, of course, but at one time or another, and peculiar inspiratory and expiratory barkings and wheezings frequently accompany the facial and body contortions. He has no organic disease that can be discovered, and all his life has been singularly free from illness, having even escaped the majority of the diseases of childhood. Various forms of treatment have been tried from time to time. He has consulted such noted physicians as Buzzard and Gowers, of London, and Charcot, of Paris, and others, but treatment of any kind has, so far, failed to produce any amelioration of the symptoms. We may therefore conclude, from the long continuance of the affection and from the failure of any form of treatment which the most competent neurologists can suggest, that the disease is the result of structural changes producing an irritation of the cells either in the cortex, one of the basal ganglia, or the pons or medulla. But in which of these regions the lesion lies we cannot determine.

Case IV.—A woman, about thirty-two years of age, came to my clinic in January, 1891. For the past twelve years she had been subject to attacks of convulsive tic affecting most of the muscles of expiration. The attacks, at times, came on every few minutes, at other times she would go for hours without a spasm. Whenever she became annoyed or irritable the spasm invariably became more severe and more frequent. There were no evidences of hysteria. With each attack the body was seen to move violently and the breath was expelled with great force from the lungs, the patient emitting at the same time a loud but brief vocal sound, somewhat similar to that uttered by a laborer as he strikes a blow with a heavy sledge, only in this case the sound had much more volume and was even more explosive in character. I prescribed for her the fluid extract of conium in doses of five drops three times a day, increasing the dose one drop daily. The greatest quantity taken at a dose was twenty-nine drops. She also received sparks of statical electricity over the cervical and dorsal spine three times a week. Improvement was noticeable in a few days, and steadily advanced. The attacks became less violent and less frequent. Anger or excitement failed to incite them, and in a few weeks they ceased entirely. She remained perfectly well during the summer and fall without treatment, but last December she began to have the spasms, feebly at first, but showing a strong tendency toward development. The same plan of treatment was inaugurated. The static sparks were given again because the patient liked them, believing the electrical application was the principal part of the treatment. Improvement began at once, and the spasms ceased entirely after a dose of eight drops was reached. I saw the patient yesterday. She was then taking fifteen-drop doses and had had no attacks for a week.

Case V.—A strong vigorous woman, about thirty-seven years of age, consulted me at my clinic in February, 1892, for convulsive tic affecting the expiratory muscles. Her symptoms were identical with those described in the history of the preceding case, only not so pronounced in character. The affection began about six months before I first saw her. She had never suffered from any serious illness; her home life was happy; she had had three children, the youngest of whom was over a year old;

there was no evidence of uterine or ovarian disease; and she had not experienced any fright or shock. In fact the cause of the disease could not be ascertained. The spasms seemed to affect almost all of the muscles concerned in expiration, and occurred probably ten times in a minute. An expiratory vocal sound always accompanied the spasm. None of the other muscles seemed to be implicated. The patient seemed to be very nervous and somewhat apprehensive. She had suffered so long without being able to obtain relief that she feared recovery was impossible. She was therefore somewhat depressed and cried frequently, but there were no evidences of hysteria. I presented her to my class, and while she was the subject of my remarks and the centre of observation the attacks were decidedly increased both in frequency and in severity. I prescribed the fluid extract of conium, beginning with doses of seven drops three times a day, and ordered the dose to be increased one drop daily. She was also given fifteen grains of bromide of sodium with each dose of conium. I saw her two days later, when she was taking nine-drop doses of the conium. The spasms were much better. While she was sitting quietly, apparently unobserved, among a number of other patients she did not have a single spasm, and even when brought before the class she did not have any until attention was directed especially to her case; even then the spasms were infrequent and very slight. Improvement continues steadily, and though the patient is still under treatment—only ten days having elapsed since the conium was first administered—she has been benefited to such a marked degree that the influence of the conium cannot be questioned, and there is every indication that the spasms will cease entirely in a few days more.

In the first and second cases, which were functional, arsenic had been used to its fullest extent and without exerting any beneficial effect. This has almost invariably been my experience with this remedy in cases of convulsive tic. On the other hand, though both of these cases were of long standing, improvement began and continued to a successful termination as soon as the influence of atropine on the one hand, and of conium on the other began to be appreciated by the affected nerve-cells. The third case was simply introduced to call attention to the fact that convulsive tic sometimes becomes organic and permanent, and that in these cases any form of treatment is futile. It also points to the fact that convulsive tic, like epilepsy, may begin as a functional disturbance, and that the continual irritation to which the motor cells are subjected may in time induce structural changes in the cells themselves, and thus change a primarily functional disease into a secondarily organic one. It is quite probable that Cases I. and II. would have in time become organic. The persistency and long duration of the spasms point that way.

The fourth and fifth cases are interesting on account of the circumscribed extent of the tic and its unusual location; the fact that after so long a duration, in both cases, the disease was relieved so promptly by conium; and the speculation as to what influence the statical electricity had on recovery. Without wishing to detract from the importance of statical electricity as a therapeutic agent, I cannot see how it could possibly have affected the course of the disease one way or another except purely in a psychical manner. Convulsive tic is unquestionably of cerebral origin and deals with the irritability of the cells connected with the affected muscles. It is difficult to understand, therefore, how any form of electricity applied to the spine, as it was applied in this case, could exert any influence at all except through the mind of the patient. The patient believes emphatically that the electricity cured her.

Zinc, either in the form of the oxide or the sulphate, has been recommended for convulsive tic, and, indeed, I have seen more than one case yield after the judicious use of this drug; but recently I have discarded it, as it does not seem to me to be as efficient as either conium or atropine.

A study of these cases shows the tendency of this affection to assume a chronic course, and also shows the powerful influence which both atropine and conium exert in speedily arresting its manifestations, and suggests strongly the advisability of prompt and effective treatment, not only to secure the comfort of the patient, but also to provide against the disease becoming permanent.

Progress of Medical Science.

Benign Infections—Œdema of the Larynx.—Dr. Merklen has recently communicated to the Medical Society of the Paris Hospital cases of infectious phlegmon of the pharynx and larynx, terminating in death. Dr. Garel reports, in the *Annales des Maladies du Larynx*, two cases of the same nature, but with this difference, that here the process was benign and terminated in cure. In both instances, young men of about an equal age were the subjects, and both gave a history of preceding affections of the mucous lining of the larynx. This laryngeal susceptibility makes one think that the mucous membrane allowed of easy penetration of pathological elements coming from without. Within the space of four or five days the œdema reached its apogee, and dysphagia was complete. Saliva, liquid and solid food were alike incapable of being swallowed. In spite of the gravity of the situation, the urine contained not the slightest trace of albumin, the laryngoscope showed the existence of an œdema absolutely different from that which one observes in the suppurating infectious forms. This is a soft œdema, trembling like jelly in the most prominent portions. It has a transparent, opaline hue, somewhat violaceous. It is thus seen to be very different from the hard œdema, which is red, and non-transparent in severe phlegmonous laryngitis. In each instance serious symptoms lasted only four or five days, and came on without any apparent cause. The author asks whether this is not the affection described under the name of primary erysipelas of the larynx. The fever and rapid remission are well in accord with this view of the case. Applications of tincture of iodine have seemed beneficial in these acute œdemas, but cocaine anæsthesia must precede it, to avoid pain and the danger of producing spasm.—*Journal de Médecine*, December 10, 1891.

Pelvic Inflammation in Women.—Dr. Potter, in a pathological study of this most interesting condition, which furnishes such a large proportion of the gynecologist's work, regards McMurtry's grouping of varieties of inflammation as about the best. It is as follows: 1. Inflammation of serous and cellular intra pelvic tissues cannot be separated clinically nor histologically, hence they cannot be properly distinguished by the terms perimetritis and parametritis. 2. The pelvic cellulitis of Emmet, which corresponds to the peri-uterine phlegmon of Nonat, is as rare as inflammation of the cellular tissue elsewhere. 3. Pelvic inflammation is, generally speaking, peritonitis resulting from disease of the ovaries or Fallopian tubes, or both. 4. Pelvic peritonitis presents every grade of activity, and is always symptomatic, never idiopathic. These inflammations are either of puerperal, gonorrhœal, or miscellaneous origin, and under the latter are included all infections of the endometrium by instruments, medicinal agents, and traumatism.—*American Gynecological Journal*, December, 1891.

Carbolic Acid Poisoning in a Hospital.—A patient in a London hospital recently died from poisoning under peculiar circumstances. A sister-in-law who had come to visit her gave her to drink from a basin standing on a table near the bed. The basin was thought by the visitor to be filled with water, but actually contained a carbolic acid solution.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, February 27, 1892.

A NEW TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.

MANY are the attempts that have been made to obtain a serviceable hip-joint for those unfortunates who have been born without one, but few are the successes which have attended these efforts. Some few cases are on record in which an apparent cure of congenital dislocation has been obtained, but it was only after a most tedious course of treatment, extending over months, and even years, trying alike to the surgeon and the patient, and impossible of application in the majority of cases, even were a successful termination less problematical than it is. Dupuytren early recognized the almost hopelessness of any treatment, and refused even to attempt a cure, being persuaded that a palliation of the condition by means of retentive apparatus was the utmost limit of the surgeon's skill. Subsequently Guérin advocated continuous traction and immobilization, a method that has given good results in a few cases in the hands of the late Buckminster Brown and others. Margary advocated resection, and obtained a seeming improvement in a limited number of cases by this operation; but his method is unscientific and his followers were few. Hoffa has recently advocated the formation of a new acetabulum by detaching a flap of periosteum; but, though ingenious, this operation is not likely to find favor in actual practice.

The most recent method is one proposed by Lannelongue in a paper read by him before the Surgical Society of Paris, on December 23, 1891. It is simply an extension of the author's sclerogenic method of treating tuberculosis of the joints by chloride of zinc injections. As has repeatedly been shown, there is in congenital dislocation of the hip more or less deformity of the head of the femur, together with absence or extreme shallowness of the cotyloid cavity, and this fact offers a ready explanation of the great difficulty of cure. The obvious indication is to form a new acetabulum, and to oppose a barrier to the upward displacement of the head of the femur. This M. Lannelongue proposed to do by creating a thick and resistant flange at the upper edge of the cotyloid cavity. He presented to the Society a little girl, three years old, upon whom he had performed the operation for a congenital dislocation of the right side. On November 17th, the child being anæsthetized and firm traction being made on the limb, the author made eight injections, of two drops each, of a ten per cent. solution of chloride of zinc, in a semicircle along the surface of the ilium, above the point where the head of the femur was maintained. There was no reaction after the operation, and ten days later one could feel a ring of bony firmness in the place where the injections were made. On December 9th, ten more injections were made upon and above this ring, in order to strengthen it. When the patient was examined at the meeting this new acetabular ridge could be plainly felt as a very hard, painless swelling, formed, M. Lannelongue claimed, in great part by a condensing osteitis.

That the deficiency of the acetabulum had been at least temporarily remedied no one could doubt, for the child walked well and the hard ridge could be felt as a barrier to the upward progress of the femoral head. But whether the condition will be permanent is a question that can only be answered by time. That the operation may prove to be a success may be devoutly wished, both for the sake of the unfortunate little patients and for that of the surgeon who would rejoice in the removal of one more of the *opprobria* of his art.

UNEQUAL AXILLARY TEMPERATURES.

IN the *Montreal Medical Journal* for January, 1892, Dr. W. H. Hattie reports a case of differing axillary temperatures which is interesting as a contribution to the literature of this puzzling subject. The patient was a man, twenty-one years of age, who had received a blow over the left temporal region, which had temporarily abolished consciousness and had been followed by symptoms of mental derangement. He was trephined and a large clot of blood was removed from between the dura and the bone, but no permanent improvement followed, and the man was sent to the Hospital for the Insane at Halifax. While in the hospital he developed a fever, the nature of which was not known at the time, but which was afterward found to be due to an exacerbation of a latent tuberculous process. The interest of the case centres in this attack of fever, for during its continuance the axillary temperature differed on the two sides of the body, sometimes very little but often as much as a degree. Almost always the temperature on the right side, the side opposite to the injury, was higher than that on the left, yet this was not invariably so, for sometimes the two sides were alike, and on a few occasions the temperature of the left side was higher than that of the right.

The existence of a heat-regulating centre in the cortex of the cerebrum is believed in now by most physiologists, but the experiments and clinical facts upon which such a belief is founded are not always in accord, and many more facts, both clinical and experimental, must be collated and studied before our knowledge of the subject can approach anything like a satisfactory stage. Dr. Hattie's explanation of the phenomena in his case lies in the assumption that a heat regulating centre actually exists in, or very near to, the motor area of the cortex cerebri, and that injury in the neighborhood may bring about more or less complete disorganization of this centre. The inconstancy of the difference between the temperatures of the two sides was a notable feature in the case, and made its solution more difficult. But we well know, the author says, that a disordered mind is liable to constant

variation, and we must look upon mentalization as a function of the cerebrum. Why, then, he asks, should not the heat-regulating function be as prone to variation when disordered as any other brain function?

MORPHINE IN HEART TROUBLES.

The use of morphine in painful aortic affections is well known. The *Semaine Médicale*, December 30, 1891, calls attention to the efficacy of hypodermic injections of morphine, the strength varying from 0.005 milligr. to 0.02 centigr., in cases of mitral disease where there is asystolia, intense pain, dyspnœa, nervous phenomena, and even impending death. It steadies the fluttering heart, strengthens its action, provokes diuresis, diminishes œdema and anasarca, and brings about a temporary resurrection when all other remedies have failed.

JAMBUL IN DIABETES MELLITUS.

A curious instance of the different effects obtained by different observers in the use of a new remedy is afforded by a review of the use of jambul in the treatment of diabetes by Mr. George Foy, in the *Medical Press* for January 13, 1892. The drug was first brought to the notice of English physicians in a communication from Mr. H. E. Ranatoola to the *Midland Medical Miscellany*, in February, 1883. He had tried the drug in four cases and reported that it decidedly lessened the quantity of urine secreted, and that the sugar disappeared in every case while the patient was taking the drug. Not much notice was taken of this paper at the time, but four years later Dr. George C. Kingsbury reported a case of great benefit from the use of the drug, in a letter which attracted wide attention. The report was republished in a number of journals, and many communications appeared from other observers detailing almost wonderful cures. Everything, Mr. Foy said, seemed to show that a valuable remedy had been discovered, when a letter was published from Dr. J. M. Coles, in which a case was related of apparent aggravation of the disease under jambul. The patient while taking the drug had the quantity of her urine trebled and the amount of sugar raised to 40 grains to the ounce. On discontinuing the jambul the specific gravity of the urine fell from 1.040 to 1 030; the amount of sugar diminished to 17 grains in the ounce, and the quantity of urine passed fell to 5 or 6 pints in the twenty-four hours. Then followed a number of unfavorable reports which seemingly proved that not only was the drug of no benefit in glycosuria, but that it was often even injurious. And that is where it stands to-day—some physicians have found jambul almost a specific, others have failed to obtain any good results even in carefully selected cases and with perfectly pure samples of the drug.

Probably as good a statement as any of the present position of the remedy in the therapeutics of diabetes mellitus was made by Dujardin-Beaumetz at a recent meeting of the Therapeutical Society of Paris, with a notice of which Mr. Foy begins his article. He had given jambul seeds in daily doses of 45 to 150 grains, but had found the results very variable. Diabetes associated with pancreatic disease was rather aggravated than benefited by the drug; but in milder cases, with a small percentage of sugar in the urine, the seeds were decidedly beneficial; the urine became lessened and the sugar disappeared. During the whole period of treatment the diet had to be carefully watched, as any recourse to farinaceous food would immediately be followed by a relapse.

THE DISTRIBUTION OF CIRCULATORY DISEASES IN THE UNITED STATES.

In the Report of the Surgeon-General of the United States Marine Hospital Service for the year 1891, Dr. Charles E. Banks continues his interesting studies in the medical statistics of the service. In the present Report he discusses the subject of diseases of the circulatory system, in which are included peri- and endo-carditis, valvular disease, arteritis, aneurism, phlebitis, varicose veins, etc.

Among nearly half a million of sailors treated for various diseases during the past ten years, 5,291, or 1.2 per cent., have been diseases of the class mentioned. The patients were distributed all over the country, and the interesting fact is brought out that the proportional number of cases and the highest ratio of mortality is on the Pacific coast, the Middle Atlantic States coming next, and the Ohio and Mississippi Valley being the lowest on the list.

Valvular diseases constituted forty-six per cent. of the cases, and here the ratio in the Pacific stations was still higher, as the following table shows:

	Total of all cases.	Valvular diseases.	Mortality.	Death-rate.
North Atlantic	38,824	326	28	8.5
Middle Atlantic	50,091	417	42	10.0
South Atlantic	75,466	397	24	6.0
Gulf	49,095	301	24	7.9
Ohio	51,135	160	13	8 0
Mississippi	43,720	204	34	11.7
Great Lakes	95,185	406	22	5 4
Pacific	27,748	243	47	19.0
Total	431,264	2,454	234	9.5

The average death-rate from valvular disease throughout the service districts is seen to be 9.5 per cent., while in the Pacific district the rate is just twice as high, being nineteen per cent., which is a striking difference. The next section in the high mortality column is the district of Mississippi, which shows 11.7 per cent., and the lowest is the Great Lakes, with 5.4 per cent.

The preponderance of aneurisms on the Pacific coast is still more striking. Although in the service there the number of patients was but one-sixteenth of the total, the number of aneurisms was one-sixth, and the mortality rate is nearly treble that of Mississippi and the Great Lakes. This is a fact which has been shown before this by Dr. John B. Hamilton, and is one to which the Pacific coast physicians might turn their attention with profit.

It may be noted that so far as the past year's statistics show, there is no excessive prevalence of syphilis in the Pacific States. If anything, there is more of it in the region of the Great Lakes.

A New Hospital for Chicago.—The Scotchmen in Chicago propose to erect a hospital to commemorate their beloved poet, which is to be called the Burns Free Hospital.

News of the Week.

Grip Mortality.—According to the State Board of Health Mortality Report just issued, out of a total of 123,878 deaths in New York State during 1891 it is estimated that 10,000 were due to influenza. The death-rate for zymotic diseases was 178 per thousand as against 169 per thousand last year. The average for the past five years is 193. The deaths from influenza were distributed over the whole State.

Living with a Ruptured Heart.—Dr. E. Rouse Rouse reports in *The Lancet* of February 6, 1892, a remarkable case of survival for a week with rupture of the heart. The man, who was fifty-two years old, short and plethoric, was playing foot-ball when he suddenly fell down in a sort of faint. In a few moments he recovered and continued his play. Soon after the game was over he had another and more severe attack, accompanied by pain in the cardiac region. When seen a few minutes later he was in a condition of partial collapse, with shallow breathing, almost imperceptible pulse, and very severe pain over the heart. He gradually improved and was able to sit up, but seven days later he had another fainting fit and died. At the autopsy the heart was found to be fatty, degenerated, and very friable, and in the wall of the left ventricle was a rupture half an inch in diameter. It seems most probable that the rupture at first was very minute or partial, not allowing the escape of blood into the pericardium, and that a week later some extra exertion caused a completion of enlargement of the rupture, resulting in escape of blood and death.

Typhus Fever in London.—In a recent report by the medical health officer of London, Mr. Shirley Murphy, it is stated that typhus fever is steadily on the decrease in that city. In 1881 there were 92 deaths from the disease, while in 1890 there were but 11 deaths reported. There are, however, probably a few more than this, some sporadic cases being occasionally overlooked.

An Hygienic Labor Congress.—The next annual meeting of the French Labor Party is to be devoted to a discussion of hygiene as it affects the workingman. The subject is to be divided into three parts—food, habitations, and workshops—on each of which there will be a general discussion, opened by a recognized sanitary authority and continued by the delegates.

The Dose of Paraldehyde.—Dr. J. Noer writes: "In the MEDICAL RECORD of February 13, 1892, you made me say: 'I have never ventured to give more than four grains at a dose, and have in second instances succeeded with two or three grains.' In this sentence grains should read grammes, second should be some."

The Medical Association of Georgia will hold its forty-third annual session in Columbus, Ga., on April 20, 21, and 22, 1892.

An Underproduction of Quinine.—In an article on the quinine trade in the *Tijdschrift voor Nijverheid en Landbouw in Nederlandsch Indie*, for October and November, 1891, Mr. Winning publishes a series of statistics upon the production and consumption of cinchona in different parts of the world, together with the estimates for the next three years. According to these figures there was more quinine consumed than was produced in 1891, and the writer thinks that the disproportion will be even greater in the immediate future. That more of the drug is consumed at the present time than is actually needed can hardly be questioned, and no doubt a very slight increase in price would speedily cut down its use and bring it within the limits of supply. The profit in cinchona cultivation has been very small for some years past, and the planters would doubtless welcome any increase in the price of bark, however small it might be. But quinine now has too many rivals, and no amount of underproduction could ever bring back the enormous prices it once commanded.

The Meanest Man in Great Britain has been found. His discovery was due to a suit to recover the amount of a bill for medical services brought by his physician. The man had ample means and held several official positions in the county and town administrations. But it appears that he was connected in some way with some extensive quarries in the place, and had been made an honorary member of the quarries' benefit club of which his family physician was surgeon. His defence was that he was entitled to the services of his family physician free, as being an honorary member of this club, although he paid very much smaller dues than the regular members. The court very promptly overruled this defence, and then he put in a more valid, but equally mean plea, and finally succeeded in avoiding the payment of about seventy-five per cent. of the claim.

Postage Stamps and Influenza.—A correspondent of *The Lancet* suggests that influenza may be spread largely through the agency of postage stamps. He recalls a number of instances in which the disease followed the receipt of a letter from an infected place, and thinks that possibly the source of the infection was the saliva used to moisten the gummed surface of stamps and edges of envelopes, the mucilage perhaps being a suitable menstruum for the development of bacilli.

The West End Medical Society.—At the annual meeting of The West End Medical Society, held February 6, 1892, the following officers were elected for the ensuing year: *President*, Dr. F. J. Bowles; *Vice-President*, Dr. G. W. Leonard; *Recording Secretary*, Dr. F. Spencer Halsey; *Corresponding Secretary*, Dr. H. G. Myers; *Treasurer*, Dr. S. V. Ten Eyck; *Pathologist*, Dr. C. N. Dowd.

Professor Wilhelm Krause has been called to fill the newly created chair of Anthropology in the University of Berlin. He was formerly, for upward of thirty years, Professor of Anatomy in the University of Göttingen.

Leprosy in the United States of Colombia.—The Colombian government has become alarmed at the rapid increase of leprosy in that country, and is considering the advisability of establishing a leper colony on one of the islands off its coast. In two of the States alone the number of lepers is estimated at 30,000.

A Prize for an Essay on Demography.—Dr. Joseph Körösi, of Buda-Pesth, has offered a prize to the value of $300 for the best essay on demography and its progress in Europe and America. The award will be made at the

opening meeting of the next International Congress of Hygiene and Demography, at Buda Pesth, in 1894. The essays, which may be in English, French, German, or Italian, must be sent in not later than January 1, 1894.

The Annual Benefit of the German Poliklinik took place on February 23d, at the Metropolitan Opera House, under the management of Mr. Augustin Daly. A very interesting programme, consisting of a comedy in English by Daly's company, as also a farce by Von Raven by Mansfield's company in German, excellent singing by Miss Koschoska, and Mr. Borosch; violin solos by Mr. Dick; cornetist Seifert; Paula Loewe in Vienna songs, and Miss Amelia Glover in America's greatest dancing. The orchestra was splendidly managed by Nahan Franko. Last, but not least, Miss Barkany must not be forgotten. Both Poliklinik and Mr. Daly are to be congratulated on the excellent result of the performance, which bids fair to lessen the mortgage of the Poliklinik buildings.

Dr. W. J. Morton has been appointed Neurologist on the Medical Board of the Randall's Island Hospitals.

Prize of the Medical Society of the County of New York.—Members of the Medical Society of the County of New York are herewith invited to compete for the annual prize of one hundred dollars, or a hundred dollar gold medal, awarded for the best essay on any medical or surgical subject, by the County Society, at its annual October meeting, the award being subject to the following conditions: 1. The competitor must be a member of this County Society in good and regular standing. 2. The competitor's identity must not be revealed until after the report of the Committee on Prize Essays has been presented at the annual October meeting, each essay in competition being designated simply by a motto, and accompanied by a sealed envelope exhibiting the same motto and enclosing the author's name. 3. If in the judgment of the committee no essay is presented that is sufficiently meritorious no award will be made. All competing essays should be sent to the chairman of the committee on or before October 1, 1892.—E. B. Bronson, M.D., Chairman Committee on Prize Essays, 123 West Thirty-fourth Street.

The Administration of Bromoform.—The usual prescription of bromoform with alcohol, syrup, and water is unsafe, owing to the insolubility of the drug in water, and the danger, therefore, that the last dose from the bottle will contain all or the greater part of the drug. In a note in the *Pharmaceutical Record* of February 11, 1892, Mr. P. W. Bedford states that he has found glycerine to be an excellent solvent for bromoform, and he recommends the following as a serviceable formula, making a stable mixture:

℞. Bromoformi..... ℥ xvj.
Alcoholis..... f ʒ ij.
Glycerini..... f ʒ xij.
Tinct. cardam. co..... f ʒ ij.
M.

If mixed in the above order it is a perfect solution, pleasant to the taste and the eye. Each fluidrachm contains one minim of the bromoform in perfect solution. The relative amount of bromoform in the formula must not be reduced in the prescription by syrup or water, though glycerin may be added in any quantity without precipitation. The particular caution is that in dispensing it there shall be no water in the mixture.

Improved Tuberculine.—A Berlin newspaper of recent date states that Professor Koch has made another important improvement in his fluid and that he believes yet that it can be made serviceable in the treatment of tuberculosis.

The Opening of the Langenbech Haus in Berlin will take place formally this spring during the annual meeting of the German Surgical Society. This is the building which has been erected as a place of meeting of all the medical societies in Berlin.

The Colombat Prize.—A sum of 10,000 francs ($2,000) has been bequeathed to the Paris Académie des Sciences by M. Colombat, for the foundation of a biennial prize in medicine, more especially for works relating to diseases of the organs of speech or deaf-mutism.

Dr. Gustav Fritsche, editor of *Medycyna*, one of the leading Polish medical journals, died recently in Warsaw, at the age of fifty-two years.

The Report of the British Leprosy Commission is said to be approaching completion. It is understood that it will prove of a somewhat reassuring character so far as India is concerned, since at the present time the number of lepers of this dependency is under what it has been said to be, 50,000. The Commissioners are also of opinion that the disease is not of an hereditary character, and its propagation by vaccination is a very rare occurrence indeed. Leprosy is, according to the report, to be regarded as a specific disease. In Norway the disease is very much on the decline, owing to the segregation and rigid rules enforced by the Government, at the instigation of the profession, and it is thought that the disease will to a certainty be stamped out in a very few years.—*Medical Press.*

Reviews and Notices of Books.

A Manual of Venereal Diseases. By E. M. Culver, A.M., M.D., and James R. Hayden, M.D. Pp. 294. Philadelphia: Lea Brothers.

This work is didactic in style and very practical. Though condensed, it brings to the front the most important points of the subject. Part I., by Dr. Culver, discusses Gonorrhœa and its complications and non-specific sores. The technique of diagnosis and treatment is well described, and numerous formulæ and cuts and descriptions of instruments are given. The author is not radical in his recommendations, taking generally a pretty safe middle ground.

Part II., on Syphilis, is by Dr. Hayden. He treats his subject in a systematic and practical manner and gives a good epitome of accepted teachings. The book seems likely to be of considerable value, to both student and practitioner.

Manual of Chemistry. By W. Simon, Ph.D., M.D. Third Edition. Pp. 479. Philadelphia: Lea Brothers.

In this edition the original division of the work into seven parts is retained. The book gives a very fair outline of what a medical or pharmaceutical student

should know about chemistry, and has the advantage of serving equally for reference-book and guide to practical work. The colored plates illustrating reactions are correct and well executed, but, though useful, should not be allowed to take the place of actual experiments. The author is a man of large experience, both as a teacher and as a practical chemist, and his work deservedly takes a good position among the many devoted to this subject.

Recent Materia Medica. Notes on Their Origin and Therapeutics. Fourth Edition. By F. Harwood Lescher, F.C.S. Pp. 114. London: J. & A. Churchill.

This little work has now reached a fourth edition. It is concise and systematically arranged and is provided with a therapeutic index which adds to its value. The various remedies introduced within the last eight or ten years are taken up in alphabetical order, and briefly discussed, the opinions of numerous authorities being quoted and references to journal articles being made. In these days, when so many remedies are being added to our list, especially through the labors of synthetic chemists, an epitome of this kind seems likely to prove of considerable value to the busy physician.

A B C of the Swedish System of Educational Gymnastics. A Practical Hand-book for School Teachers and the Home. By Hartvig Nissen, Instructor of Physical Training in the Public Schools of Boston, Mass.; Instructor of Swedish and German Gymnastics at Harvard University's Summer School, 1891; formerly Instructor of Physical Culture at the Catholic University, Washington, D. C., etc. With 77 Illustrations. Philadelphia and London: F. A. Davis. 1891.

This is a work intended to guide the teachers of Swedish gymnastics in the school or home circle. The first two chapters are devoted to an explanation of the different exercises and of the mode of employing them, together with a definition of the terms used. The third chapter contains a table of graduated daily exercises for a course of thirty-three weeks. The explanations are simple and easily understood, and the book appears to be well adapted for use as a primary text-book of Swedish educational gymnastics. The author is an authority on the subject treated, and he has done good service to the cause of health in school children by the preparation of this little book.

Text-Book of Practical Anatomy. By Henry C. Boenning, M.D, Lecturer on Anatomy in the Philadelphia School of Anatomy; Demonstrator in the Medico chirurgical College. etc. 8vo, pp. 487. Philadelphia: F. A. Davis. 1891.

The object of this work is to assist the student in dissection as well as in the class-room. It is not a compilation but has been made up from the author's own work. We do not look for much heterodoxy in works on anatomy, and so far as the present one is concerned we have to commend its simplicity of style, the clearness of most of its woodcuts, and the thoroughness with which the ground is covered.

Compend of Physiology. By William J. Watkins, M.D. Pp. 243. Published by the Author at Louisville, Ky. 1891.

We are informed on the title-page that this is the first edition. A second will probably not be called for. The author has endeavored by the "question and answer" plan to comprise the whole of physiology within these narrow limits. So far as an outline thereof is concerned there are other books of the class which we think far better. His questions are often useless and the answers too short to be of any service to the student. Such books do the cause of medical education more harm than good.

Diseases of the Liver. By J. Compton Burnett, M.D. Pp. 186. Philadelphia: Hahnemannian Publishing House. 1891.

This is a compilation of clinical histories of various forms of liver disease, with a general discussion of the effects thereon of the various agents in the homœopathic pharmacopeia.

Saunders's Pocket Formulary. By William M. Powell, M.D., Author of "Essentials of Diseases of Children," Associate Editor of the "Annual of the Universal Medical Sciences," Attending Physician to the Children's Seashore House for Invalid Children, and Mercer House for Invalid Women, at Atlantic City, N. J., etc. Pp. 261. Philadelphia: W. B. Saunders.

This little book, that can conveniently be carried in the pocket, contains an immense amount of material. Besides the hundreds of prescriptions for every conceivable complaint, compiled from the best authors and also including the newer preparations of medicine, there is an appendix containing posological table, formulæ, and doses for hypodermic medication, poisons and their antidotes, diameters of the female pelvis and fœtal head, diet list for various diseases, obstetric table, materials and drugs used in antiseptic surgery, etc. It is very useful, and, as the name of the author of each prescription is given, is unusually reliable.

The Doctor's Ledger. Copyrighted and Published by C. A. Price, Jersey City, N. J.

This is a handsome and very convenient ledger for a doctor's use. Its keeping is simplicity itself, and yet a glance shows the exact status of any account.

Syllabus of the Obstetrical Lectures in the Medical Department of the University of Pennsylvania. By Richard C. Norris, A.M., M.D., Demonstrator of Obstetrics, University of Pennsylvania; Physician to the Methodist Episcopal Hospital, Obstetrical Registrar Philadelphia Hospital. Second Edition. 12mo, cloth, pp. 198. Philadelphia: W. B. Saunders.

This is the second edition of a popular work of immense value to students. It is an abstract of obstetrical lectures interleaved and so arranged as to give a good outline of work to be filled out in the class-room. The second edition has notable additions to the chapters on infant feeding, pathology of the puerperium, obstetric operations, and dystocia.

The History of Circumcision from the Earliest Times to the Present; Moral and Physical Reasons for its Performance. With a History of Eunuchism, Hermaphrodism, etc., and of the Different Operations Practised upon the Prepuce. By P. C. Remondino, M.D. (Jefferson), Member of the American Medical Association, of the American Public Health Association, of the San Diego County Medical Society, etc. Pp. 346. Illustrated. Philadelphia and London: F. A. Davis.

This is No. II. in the Physicians' and Students' Ready Reference Series. The book serves a double purpose, that of completely elaborating a useful subject, and at the same time being rich, rare, and racy reading, something the tired practitioner can sit down to and thoroughly enjoy. The title is an index of the contents. Those chapters that treat of the relations of the prepuce with syphilis, phthisis, cancer, calculi, neuroses, and urinary diseases, are worthy of special praise and deserve careful reading.

An Honest Confession is Good for the Soul.—Koch stated in a recent communication that the action of tuberculin was not exactly what it should be.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 8, 1892.

THE PRESIDENT, GEORGE L. PEABODY, M.D., IN THE CHAIR.

Embolism of the Pulmonary Artery in Childbed.—DR. E. L. PARTRIDGE read the paper (see p. 234).

DR. F. P. KINNICUTT thought he had once seen a case of embolism of the pulmonary artery in childbed which recovered. The attack came, as usual, with great suddenness and with all the symptoms which the author had described, lasted several days, and disappeared. During its presence the patient's condition was most alarming. Nothing had been done, such as giving a vaginal douche, etc., which might have caused the attack.

DR. BEVERLEY ROBINSON recalled some observations on clots in the right heart and pulmonary artery which he had made when interne in a hospital for children in Paris, the cases occurring in children who had died of diphtheria. The observations had formed the basis of his thesis at that time. He could not say that they had any special bearing on Dr. Partridge's paper, but he would state that in children who had died of diphtheria he often found blood-clot in the right heart, which also often extended into the pulmonary artery, and he was unable to determine at the time when the latter condition existed, whether it was due to damming back of the blood in the artery because of complicating pneumonia, or to anæmia, or some other cause. He also noticed some change, in part of the cases, in the tricuspid valve, but made no effort to explain it. He could not recall having seen a positive case of pulmonary embolism, although he had seen several cases, in which that condition was suspected. It was doubtful, he thought, whether we could differentiate positively during life between pulmonary embolism and thrombus in the right heart cavity. If there were conditions favoring embolism, and great cardiac distress arose, we might assume that the condition was one of pulmonary embolism, but that was as near as we could arrive at a diagnosis ante mortem. He had seen no case in childbed.

DR. J. WEST ROOSEVELT said that, so far as embolism of the pulmonary artery in childbed was concerned, he knew nothing. As to the artery or one of its branches going to a considerable portion of a lung becoming blocked by an embolus proceeding from a uterine sinus or any vessel of ordinary size, he did not believe it was possible. He had never seen but one case of embolic obstruction of the larger pulmonary arteries. It occurred in a patient who had erysipelas of the left side of the face and an enlarged gland on the left side of the neck. The erysipelas was subsiding when the patient suddenly began to have cough and prune-juice expectoration; temperature, 104° to 107° F.; little dyspnœa; dulness on the left side of the chest from top to bottom. The patient showed signs of intense sepsis, and died between one and two days. The left pulmonary artery was found thrombosed, including the larger branches. The skin had been somewhat purplish. He only mentioned the case as illustrating to what extent thrombosis of the pulmonary artery might exist, and yet not cause very marked dyspnœa. It was inconceivable how a large pulmonary artery could become obstructed by a thrombus or embolus, and the obstruction be removed without first breaking down of the lung-tissue, for the pulmonary arteries were absolutely terminal.

With regard to the physical signs, he might say that in the few cases of pulmonary thrombosis or embolism following experiments which had come under his observation, they were definite enough. Extensive hemorrhagic infarctions would be followed in a short time, say an hour or two, by complete splenification of the involved lung, showing absolute dulness and absence of breathing. If it were possible for an embolus of sufficient size to reach and obstruct the main pulmonary artery, it would, of course, rapidly cause a fatal termination. It would have to be derived from as large a vessel as the iliac vein in order to block a branch of the pulmonary artery of considerable size. He thought it was assuming a great deal to say that a fibrinous clot found in the right side of the heart had been due to a pulmonary embolus with damming back of the blood. He had seen a decolorized clot in the heart in a few cases where the patients had died without a single symptom of interference with the heart's action. In one case the autopsy was made within an hour after death, and in another within an hour and a half. Clotting would occur very soon post mortem.

As to the symptoms in the cases related in the paper, he thought it was quite possible they had nothing to do with clotting in the pulmonary artery at all, but were due to some fault in the heart. While a clot as large as one's little finger might occlude a pulmonary artery and cause dyspnœa, yet with the dyspnœa there would also be evident physical signs. But multiple embolism might occur throughout the lungs and cause no symptoms during life. He had a specimen in which three-fourths of the lungs were shut off by hemorrhagic infarctions, yet during life there had been no symptoms of obstruction. It seemed, then, that in reported cases of embolism of the pulmonary artery in childbirth, there could have been but the following sources of the embolus, namely, the superior or inferior cava, or, more likely, the right heart; for in those places only could an embolus form large enough to produce such occlusion.

DR. CLEMENT CLEVELAND said he had never seen a case of embolism of the pulmonary artery, but it seemed to him the author's views on the etiology of the condition were most plausible. The woman had received a uterine douche. Violent contractions probably took place, clots were forced out together with serum, and inasmuch as clots could be dislodged elsewhere and carried to distant parts, he knew of no reason why they might not start from the uterine or ovarian vein and proceed to the pulmonary artery.

DR KINNICUTT added that, whatever might be the mechanical difficulties in accounting for embolism of the pulmonary artery, it was still true that the symptoms described by the author did sometimes occur in childbed, among them being profound and unusual cardiac distress. And such cases occurred, too, where the heart was apparently perfectly normal. Seeing the cardiac distress and uterine condition occurred together, it seemed to him there must be some anatomical relation between the two, and it was not improbable that embolism of the pulmonary artery did actually take place.

DR. ROOSEVELT remarked that he did not wish to say an embolus might not have been present, but he did not think one from the uterine sinus could occlude the pulmonary artery.

DR. PARTRIDGE, in closing the discussion, said he did not suppose that a clot arising from the ovarian, or even femoral or iliac veins, could of itself, without other conditions, cause sufficient obstruction of the pulmonary artery to prove fatal. But immediately after lodgement of the embolus, the conditions were such that thrombotic deposits began to take place back toward the heart and in the branches of the artery, until death ensued. Moreover, if he understood Dr. Roosevelt correctly, he had spoken of cases where the clot in the right heart had been insignificant as compared with that in the pulmonary artery, which might point to the lesion in the artery as being primary and fatal. The heart obstruction must have been insignificant, for the patients had died without a cardiac murmur of any kind. Pathological and clinical facts would outweigh theory. In about half of the reported cases there had previously existed thrombosis of the femoral or iliac vessels, which made it more than

probable that the cardiac and pulmonary symptoms had a similar origin. As to the size of the uterine vein after labor, it had a diameter of that of a large goose-quill, probably of about the size of the third or fourth division of the pulmonary artery. But it was not so much a question of the size of the embolus, but the fact that its lodgement was followed by rapid coagulation of blood and deposit of clot backward toward the heart.

The discussion on the treatment of typhoid fever was then taken up, to be continued at the next meeting, when the full report will appear.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 23, 1891.

H. P. Loomis, M.D., Vice president, in the Chair.

Rupture of the Cystic Duct.—Dr. George P. Biggs presented specimens showing the rupture of the cystic duct. The patient, a colored woman, fifty-nine years old, had had, one month previous to her last illness, an attack of cramp-like pains in the upper part of the abdomen, and these were similar to those which ushered in the present illness. Four days previous to her admission to the New York Hospital she was suddenly seized while at work with cramps in the upper part of the abdomen, and on the following day this pain was succeeded by a soreness which steadily increased in severity. On the first day there was a chill, followed by fever, and this was repeated on the third day. The prominent symptoms were vomiting, constipation, abdominal distention, dyspnœa, and prostration. At the time of her admission the conjunctiva was markedly jaundiced, the chest was full of moist râles, and the heart action was so rapid and feeble that the heart-sounds could not be heard. The abdomen was distended and tender. Pulse, 96; respirations, 30; temperature, 101.4° F. On the evening of the same day, her temperature rose to 104.4° F., the respirations reached 52, and the pulse 132. She died the same night, the temperature just before death being 107.2° F.

At the autopsy, which was made fourteen hours after death, the abdomen was found to be greatly distended and the peritoneal cavity was filled with a dark brown, bile-stained fluid, having a slightly fecal odor. The intestines were matted together by abundant recent fibrinous exudation, and the liver and spleen were united by recent adhesions. The vermiform appendix and cæcum were normal. The pleural cavities each contained three ounces of thin serous fluid, and the lungs were congested and œdematous. The heart-muscle, though soft and flabby, presented no apparent structural change. The orifice of the common bile-duct was about the size of a goose-quill, and just inside of the opening a large gall-stone was impacted. It was ovoid in shape and about one and a half centimetre in diameter. When pressure was made on the collapsed gall-bladder, a few drops of bile and a small quantity of gas escaped into the peritoneal cavity from the cystic duct, just at its origin at the gall-bladder. An oblique perforation was found at this point, which readily admitted a small probe. Upon opening the gall-bladder and gall-ducts the point of perforation was found to be in the base of an old ulcer, about three-quarters of a centimetre in diameter, situated in the cystic duct just below the neck of the gall-bladder. The edges of the ulcer were hard and smooth, and its base necrotic. Careful search at the point of perforation in the gall-bladder, the gall-ducts, and in the peritoneal cavity failed to show the presence of any other gall-stone. The cystic, hepatic, and common ducts were all much dilated, the latter admitting a cylinder one centimetre in diameter. The gall-bladder, which was collapsed, measured five centimetres in diameter. Its muscular walls were considerably hypertrophied and its mucous membrane thickened from chronic inflammation. At its neck was a superficial ulceration. The liver was of a greenish-yellow, the left lobe being much atrophied. The bile ducts were distended with greenish bile, and the liver-cells showed considerable fatty change. The ulcer through which the perforation had occurred was apparently an old one, and must have been produced by the stone found at the opening of the common duct. The hypertrophy of the walls of the gall-bladder prevented its dilation and caused great distention of the gall-ducts.

Dr. H. P. Loomis thought the specimen one of unusual interest. In a recent review of the literature of diseases of the gall-bladder and ducts he did not recall having seen the report of a similar case.

A Myxo-chondro-sarcoma of the Leg.—Dr John S. Ely presented a section of a myxo chondro-sarcoma of the leg. The specimen had been removed from a woman, twenty years of age, and was of interest both on account of the rapidity of its growth, and the details of its structure. The patient had suffered from pain in the calf of the leg in May, and soon afterward she noticed a lump, which grew so rapidly that by the middle of July the tumor was removed by operation and the bone thoroughly scraped. Dr. John S. Thacher reported the growth to be a myxo-chondroma, "with here and there a suggestion of sarcoma." The growth quickly recurred, and on September 7th the greater part of the fibula was removed along with a tumor measuring 12 x 5 x 4 ctm.

The specimen presented to the society was taken from the periphery of this growth. It showed much tissue which was unquestionably sarcomatous, but mucous and cartilaginous tissue predominated. This is interesting in connection with the belief entertained by many that chondromata frequently recur as sarcomata. As both belonged to the connective-tissue group of tumors, there is nothing inherently impossible in such a supposition, and it is known that in very rapid growth cells are not uncommonly diverted partially from their ordinary destiny and modified in their function. But, on the other hand, it seems unlikely that a cell so highly differentiated as the cartilage cell should undergo so readily the decided change which would be involved in its conversion into a sarcoma cell, and therefore the speaker inclined to the opinion that the sarcomatous element in these cases is present from the first, though undoubtedly overshadowed by the more abundant tissues.

The specimen also illustrated the various stages in the growth of cartilage. At the periphery of the tumor it is represented by little more than a mass of cells huddled together, without visible intercellular substance. By examining in succession the more central portions of the tumor one can see, as the result of the deposition of a hyaline matrix about the cells, the gradual merging of this into a tissue closely resembling normal hyaline cartilage.

Stated Meeting, October 14, 1891.

H. P. Loomis, M.D., Vice-president, in the Chair.

Simple Photo-micrography.—Dr. F. Abbott, Jr., presented, on behalf of Dr. J. M. Byron, a number of photo-micrographs as illustrations of what can be done in this line of work without any elaborate or specially designed apparatus. An ordinary microscope and camera were employed, the source of illumination being direct sunlight transmitted through yellow glass. Moderately quick acting orthochromatic plates were used for the production of the photographic negative. The average exposure was five seconds, and the magnifying power was about 1,200 diameters.

The Vice-president remarked that he noticed among the photographs one of the lepra bacillus. So far as he knew, this was the first time this bacillus had been photographed in this country.

Intestino-peritoneal Septicæmia.—Dr. H. P. Loomis presented specimens from a case of intestino peritoneal septicæmia. The patient, a man, thirty-eight years of

age, while sitting in a chair, was shot with a 38 calibre pistol-ball, which entered the left lumbar region and passing over the descending colon was deflected upward by the left ilium into the lumbar muscles. Six hours after the injury laparotomy was performed at Bellevue Hospital by Dr. Woolsey, and eleven perforations in the jejunum and ileum were closed by horse-hair sutures. The patient recovered well from the shock of the operation, and during the next three days had but little elevation of temperature and only such pain as was attributable to the wound of the abdominal parietes. There was some nausea, but no vomiting. On the fourth day the temperature suddenly rose to 105.5° F., accompanied by a small and rapid but not wiry pulse; the abdomen was moderately distended but painless, and there was constant nausea and some vomiting. The patient was perfectly rational up to his death on the evening of the fourth day after the injury. At the autopsy, which was made ten hours after death, the abdominal cavity was found to be free from any effusion or evidence of peritonitis, and there was no leakage from the intestinal wounds, which appeared healthy.

The clinical history and the post-mortem appearances seem to place this case among those recently described by Verchère under the name of "intestino-peritoneal septicæmia."[1] In these cases death is supposed to be due to the escape into the peritoneal cavity, at the time of the perforation of the intestine, of either intestinal gases or of microbes. The result is the formation of ptomaines, which, when absorbed, give rise to the fatal septicæmia.

Rupture of the Uterus.—Dr. H. P. Loomis presented a specimen from a case of rupture of the uterus. The patient was a woman about thirty-five years of age, who, when brought into Bellevue Hospital, was so seriously ill that a thorough examination was not made. She was found to be pregnant at full term, and from the odor of the vaginal discharge and the presence of some fever it was supposed that there was puerperal fever and a dead, macerated fœtus. The case was seen by several physicians; and Dr. Lusk, who was present at the time, without making a personal examination, advised turning and immediate delivery. Just as the attending physician began to turn the child, the woman suddenly went into collapse, and died on the table.

At the autopsy, made about thirty hours after death, the fœtus was found free in the abdominal cavity. There were no evidences of peritonitis. On one side of the uterus, near the utero-vaginal junction, was a rent almost large enough to admit the closed fist. On opening the uterus, there were no signs of septicæmia found, and nothing to explain the odor of the vaginal discharge. At the symphisis there was a large bony excrescence projecting into the pelvis, and the pressure of the contracting uterus upon this may possibly account for the rupture. There seemed to be no degeneration of the uterine walls.

Dr. George C. Freeborn suggested that during the manipulations incident to turning the cervix, which appeared to be very much thinned, might have been thrown toward one side, and so forced against this bony prominence at the symphisis.

Dr. R. H. Sayre remarked that the case appeared to be an argument in favor of the view now entertained by some modern gynecologists concerning the greater safety of Cæsarean section in these difficult and obscure cases, as compared with version.

Dr. Warren Coleman said that he was present at the time version was attempted, and the operator had told him that at the time the fatal collapse occurred his hand was in the uterus and was grasping the foot of the fœtus. Owing to the fact that no thorough examination had been made previously, the physicians were unable to agree as to whether or not the rupture had existed prior to the attempt made to turn the child.

Traumatic Suppurative Pleurisy.—Dr. H. P. Loomis also presented the lungs from a case of traumatic suppurative pleurisy, with perforation of the diaphragm and discharge in the inguinal region. The patient, a boy of sixteen years, was in perfect health up to five weeks before his death. His illness began by his being struck by a base-ball on the right side, in the outer infrascapular region. He soon began to suffer from pain in the right side, accompanied by cough and slight fever. His condition became rapidly worse; there was loss of flesh, high fever, cough with foul-smelling expectoration, and ten days before his death an abscess discharged in the right inguinal region, just above Poupart's ligament. As the glands in this region were enlarged, the suppuration was supposed to be of tubercular origin, and the case was considered to be one of acute phthisis.

At the autopsy, which was made eight hours after death, the right pleural cavity was found to contain a quantity of thick pus. The abscess track extended through an opening in the anterior portion of the diaphragm over the anterior surface of the liver, and the outer and anterior surface of the ascending colon, terminating at the opening above Poupart's ligament. It was shut in by adhesions, and there was no general peritonitis. The lower lobe of the right lung was consolidated, and grayish areas of consolidation were scattered through the right middle lobe and the left lower lobe. The gross appearance was like that of tubercular pneumonia, but the microscopical examination showed the pneumonia to be of the catarrhal form, unaccompanied by bronchitis.

The manner in which the pleural cavity was drained is worthy of note, as was also the absence of any general peritonitis. The clinical history and the physical signs closely simulated those of acute pulmonary tuberculosis, with the formation of a cavity on the right side. When the case was first seen there was but little pus in the right pleural cavity, and no succussion could be obtained.

The Society then went into executive session.

Stated Meeting, October 28, 1891.

H. M. Biggs, M.D., President, in the Chair.

Effects of Dead Tubercle Bacilli on the Body-cells.—Dr. T. Mitchell Prudden presented a series of specimens illustrating the effects of dead tubercle bacilli on the body-cells. He and Dr. E. Hodenpyl had made an experimental study of these effects, and he desired to present a brief outline of the work. For some time past it has been known that certain substances when brought into contact with living cells had the power of drawing these cells to them, or of driving them away. This power does not seem to be dependent upon the tactile sensibility of living cells, particularly the leucocytes, but upon chemical action. This phenomenon has been given the name of "chemotaxis," and is designated as *positive* or *negative*, according as the cells are attracted or repelled. Many substances were tested in regard to their chemotactic power, and particularly the bacterio proteins. It has been shown that when bacteria die, and their bodies disintegrate, they have the power of attracting leucocytes, and it has also been shown that under certain conditions dead and disintegrating bacteria stimulate certain cells to proliferation.

About one year ago it had occurred to Dr. Prudden and Dr. Hodenpyl that, owing to the peculiar effect which the tubercle bacillus had upon the body, it might prove instructive to investigate the effects produced by the bacterio-protein of this bacillus. The experiments were begun by securing large amounts of cultures of the tubercle bacilli. Ordinarily, the time required to kill this bacillus by the usual sterilizing process by steaming is fifteen minutes, but to make sure that their vitality was completely destroyed they were subjected to the process of steaming for varying periods, the shortest time being two and a half hours, the longest five hours, and the average four

[1] Revue de Chirurgie, 1888, p. 559.

hours. Strange to say, the bacilli were found to stain just as well after this process as before, and, in short, they were morphologically unchanged. Great care was taken to remove from the outside of these bacilli all traces of the culture material and of chemical products by subjecting them to repeated washing and filtration.

Having certainly killed the bacilli, and freed them from extraneous substances, they were introduced into the body in various ways—beneath the skin, into the peritoneal and pleural cavities, into the blood-vessels, and into the lungs through the trachea. The first effect noticed was a marked positive chemotactic action exerted upon the leucocytes. The second effect was to stimulate to proliferation the body-cells in the region in which the bacilli had lodged; thus, if they lodged in the blood-vessels they would excite proliferation of the endothelium, if in the connective tissue a proliferation of the connective-tissue cells, if in the epithelium of the lungs a proliferation of these cells. In the latter case, not only was a distinct epithelioid tissue produced, but a stroma was formed, and in about ninety per cent. of the cases giant-cells were developed. The more finely divided the culture material the smaller would be the resulting lesion. Contrary to expectation, not once has caseous degeneration been observed in the many animals subjected to these experiments. The nearest approach to it has been an occasional necrosis of the leucocytes, which showed itself first in the body of the cells, the nuclei remaining intact, which is not the case in true cheesy degeneration. There is a gradual but steady conversion of these new areas into fibrous tissue, and as they change into cicatricial tissue contraction takes place, and the blood-vessels still remaining are made to gape widely. In a few cases calcareous deposits have been noticed in the newly formed tissue. Sometimes these areas will remain as epithelial nodules for two or three months.

The process which has just been described is probably due to the action of the bacterio protein, for at first the bacilli are well formed and can be stained, but gradually they become granular, and finally disappear, and about this time all active change seems to have ceased.

From the observations thus far made it would seem probable that the morphological changes produced in the body by the tubercle bacilli are due to the setting free of the bacterio-protein, for the lesions produced by this substance are, except for the cheesy degeneration, almost identical with those seen in tuberculosis. The bacilli are constantly being reproduced in tuberculosis, but there is no reason for believing that they are long-lived. It is true that no explanation has yet been offered for the caseous degeneration and the toxic effects occurring in tuberculosis; but it is not improbable that inoculations of bacterio-protein of the dead tubercle bacillus along with some material extracted from the cultures may give rise to these two as yet unexplained effects.

Dr. Prudden presented both gross and microscopical specimens to illustrate the experiments which he had just described. The specimens under the microscopes showed the first effect of the inter-tracheal injection of the dead bacilli, next the formation of the zone of new epithelioid-celled tissue and giant-cells around the collected leucocytes, and the gradual development of connective tissue.

In answer to a question from Dr. H. P. Loomis, as to whether similar results might not follow the injection of inert substances, Dr. Prudden said that they had made a long series of control experiments with inert substances, such as lycopodium and carmine, and with irritating substances, like red pepper, and with various bacteria, and had obtained entirely different results. The gathering of the leucocytes only initiated the process, and was not an essential feature. He knew of no other injection which had resulted in this cell proliferation. The experiments just described might have some bearing upon a subject which had been frequently discussed in the Society, viz., cases which they had been accustomed to call "healed phthisis." In these, nodules had been found at the apex, containing tubercle bacilli which could be stained. It was possible, in the light of these recent experiments, that such lesions might be produced by dead bacilli, or at any rate were not foci for fresh infection.

The President asked if inoculations with the material from cheesy nodules had not in almost all instances produced tuberculosis.

Dr. Prudden replied that it had done so in many instances, but it could not be produced at will in this way in every instance. He thought that if a nodule pursued the course described in the experiments, and did not undergo cheesy degeneration, it might be regarded as a pseudo-tubercle.

A Method of Rapidly Collecting Deposits for Microscopical Examination.—Dr. George C Freeborn said that at the last meeting of the Congress of Internal Medicine, held at Wiesbaden last April, Dr. Littman, of Berlin, had presented a centrifugal machine adapted for the rapid separation of deposits from fluids for the purpose of microscopical examination. In the machine presented at that time a speed of nine thousand revolutions per minute could be obtained. Dr. Freeborn said that he desired to present to the Society a home-made machine of this description, which, although capable of only about nine hundred and fifty revolutions per minute, had answered admirably the purposes for which it was devised. He had taken the necessary gearing from an ordinary rotary drill, and this combined with a table clamp and a disk of sheet brass attached to the end of the spindle were all the essential parts. To the periphery of the disk of brass a number of wire gauze cylinders are pivoted, so as to hang vertically when the machine was at rest, but when the machine was in rapid motion, they would be thrown outward, just as are the balls of an ordinary steam engine governor. The fluids from which the sediments are to be collected are contained in small glass tubes, conical at the bottom. These tubes are introduced into the gauze cylinders, and the disk is then revolved rapidly. In this way, the sediment is thrown to the bottom of the collecting tubes, and may then be removed from them by means of a long and very slender capillary pipette. In some of Dr. Littman's experiments with urine it was found that by twirling the tube for four minutes, then decanting the urine into another tube, and repeating the process twice, the urine could be rendered absolutely free from sediment. Crystals could of course be very readily collected in this way, and enough casts for diagnostic purposes could be obtained in five minutes with this machine.

In order to demonstrate the action of his machine, Dr. Freeborn employed three different mixtures: one of lime-water holding in suspension very finely divided carbonate of lime, another of blood mixed with normal salt solution, and the third containing water and carmine. Putting the machine into action for about half a minute was sufficient to show an appreciable quantity of sediment at the bottom of the tubes. In ordinary urinary analysis, not only would this new method enable the microscopical examination to be made about twenty-four hours sooner than formerly, but it would effectually prevent the decomposition of casts which was liable to occur when the urine had to stand for many hours in order that the deposit might settle.

Dr. J. S. Thacher presented a bladder showing the openings of four ureters. He also presented a heart showing a decided tricuspid and mitral stenosis and a very marked aortic stenosis. The history was interesting on account of the frequent variations in the cardiac murmurs. This was quite remarkable, even after making due allowance for errors in observation.

The patient gave the ordinary history of endocarditis, and of rheumatism, occurring at the age of thirty-six. Four years before death the first marked symptoms of cardiac disease were developed. The first note about the murmurs was, that there was a basic systolic murmur, later, a loud, double basic murmur with its maximum in-

tensity over the pulmonary area, still later, that there was a double murmur at the base and a mitral systolic mur mur, transmitted slightly toward the axilla. Next, there was heard a double murmur at both base and apex. A few months after this it was noted that there was a double aortic and a double systolic murmur at the apex; later, a double murmur at the base, while at the apex the sounds were confused; next, there was a systolic murmur at the base, and a double murmur at the apex, which was conveyed down toward the sternum, and also that there was a diastolic murmur present. Finally, it was noted that there was a double murmur at both base and apex.

The patient had been tapped fifteen times in a period of one year and a half, and at each tapping from twelve to fifteen pints of fluid were removed. At first, the liver was noted as being of normal size, one month later, as three inches below the free border of the ribs, with considerable fluid in the pleural cavity. A few months after this, the record states that "the liver was pushed up," and some months later, after a severe attack of pain in the region of the liver, accompanied by elevation of temperature, it was stated that the liver was again several inches below the free border of the ribs. This was made shortly before death, and yet at the autopsy the liver was found to be of normal size. Dr. Thacher said that he had frequently noticed that where competent observers had recorded the liver as being enlarged, the autopsy had shown it to be normal in size and weight. In some of these cases, the enlargement might have been due to congestion, which subsided at the time of the patient's death, and so caused a rapid diminution in the size of the liver.

Dr. H. P. Loomis said that apparent changes in the size of the liver were frequently dependent upon the distention of the intestines, causing the liver to turn upward, and so give a marked diminution in the area of dulness.

Rupture of a Pelvic Hæmatocele during Delivery.—Dr. H. P. Loomis presented the uterus and vagina from a woman, thirty one years of age, who had been attended by a midwife, and delivered instrumentally. She was confined three days before her admission to the hospital and the husband states that the labor was difficult and that an operation was required. On admission, her condition was such as to preclude a thorough examination, and she died twelve hours later. At the autopsy, the abdominal cavity was found filled with bright fluid blood, and with large clots in the pelvis, on the left side, and behind and around the descending colon. There was no peritonitis. The hand could be passed through Douglas's cul-de sac into the abdominal cavity. This rupture had evidently been attended by a profuse hemorrhage which had caused death. Behind the lower portion of the upper part of the vagina was found the old and ruptured cavity of a pelvic hæmatocele, which was evidently extra-peritoneal. The size of the hæmatocele was about that of an orange. There was also a small dermoid cyst of the ovary, which, however, was only incidentally of interest. It was difficult to say whether the rupture was caused by the pressure of the child's head, or by instruments.

The Society then went into executive session.

The International Health Association will meet in the city of Mexico, in November, 1892. The Association at present comprises the United States, Canada, and Mexico, but it is hoped that the Central American Republics will also join it at the next meeting. Dr. Watson, the secretary of the Association, while travelling in Mexico, induced the health authorities of that republic to enter into a plan of international and interstate notification of the outbreak of contagious and infectious diseases, such as already exists between the United States and Canada, by which every state, province, and town are immediately advised of the appearance of disease in any foreign locality, of its nature, the number of cases, and other particulars.

Clinical Department.

A CASE OF NASAL REFLEX.

By W. H. BATES, M.D.,

NEW YORK.

The patient suffered very much, was relieved by simple treatment, and was kept under observation a sufficient length of time to confirm the diagnosis.

Miss J——, an art student, aged eighteen, complained that she could not use her eyes for near work without great fatigue. After reading for a short time, she had considerable headache. In consequence she was compelled to stop her studies. Tonics and rest of the eyes gave her no relief. The condition grew steadily worse.

August 15, 1887.—Patient sees double at times, from insufficiency of the interni. Several weeks ago atropine was used and the eyes found to be nearly normal, requiring no glasses.

September 18, 1887.—The eyes are no better. Headaches still severe. After the application of cocaine to a sharp projecting point on the left side of the septum, the eyes felt better and the patient could read with more comfort. Ten minutes later, when the effects of the cocaine had passed off, the tired feeling in the eyes returned; cocaine was applied to other portions of the nose without relief. It seemed that this sharp spur was causing a reflex irritation in the eyes. Under cocaine this sharp point was removed with the nasal saw. Immediately the patient stated that the eyes felt very much better. She could now read diamond print with perfect comfort.

January 22, 1888.—Four months later, no more trouble with her eyes or head and has resumed her studies. It is interesting to note that the insufficiency of the interni is still present and that she has had several colds in her nose without affecting her eyes injuriously.

December 10, 1891.—Four years later the patient reports that she has had no trouble with her eyes until about three weeks ago. Last summer her nose was injured. A physician inserted at this time a probe into the left nostril to straighten the nose. The doctor was not sure that the nose was broken. Now she suffers so much from pain in her eyes that she is unable to work. The insufficiency of the interni is still present. An examination of the left nostril shows some projecting tissue on the site of the old operation. Under cocaine this was removed. The eyes felt relieved immediately.

January 31, 1892.—In a letter the patient reports that she has returned to work and that her eyes still feel relieved.

131 West Fifty-sixth Street.

IS PUS ABSORBED BY THE SYSTEM?

By FRANK S. LOW, M.D.,

PULASKI, N. Y.

This question has often been asked and perhaps never has been proven beyond a doubt. Clinically it is of great importance to the surgeon and should be more thoroughly studied, for if it is taken up by the absorbents and either converted into new tissue or eliminated through the various excretory organs, the necessity of using the knife or aspirator is largely reduced.

The literature of the subject is very meagre, and I have not been able to get much light on the subject through any authors which I have consulted, and the few remarks which I shall offer for consideration will be based mostly on my own somewhat limited experience.

Pus, as defined by Dunglison, is a secretion from inflamed textures, and especially from the areolar membrane. It is almost always of the same nature, whatever may be the part it proceeds from, and is of a yellowish-white color, opaque, inodorous, and of a creamy appearance, and

consists essentially of two distinct parts, pus corpuscles and a colorless aqueous fluid called liquor puris. How is this substance formed, and what seems to be the purpose of nature in forming it?

Let us take a few familiar examples to illustrate: A person receives an injury—say a severe blow in the leg. The parts become swollen and red from obstruction in the circulation as it existed previous to the injury, also by the instinctive desire of nature to carry more blood to the injured part for the purpose of repair. Thus we have a congested condition of the capillaries, which being unable to unload themselves through the natural channels, the more liquid part of the blood oozes out into the surrounding parts and with the white corpuscles of the blood forms pus. This process still going on from the same cause, there is obstruction in the circulation of the blood, with the heart's action still furnishing more material, the pus compresses the surrounding tissues and forms a cavity which we call an abscess, and when filled with nothing but pure pus is absolutely harmless as far as blood-poisoning is concerned, and is only painful by the pressure that it produces on the surrounding tissues. If by reason of its size and position it destroys any living tissue which mingles with the pus, decomposition of the whole mass takes place, and we have then the danger of pyæmia.

Let us study the natural course of this collection of pus. It seeks the easiest way to escape, and if near the surface will soon, by absorbing the tissues, reach the skin, which, being deprived of its blood supply, dies and forms a slough, through which the contents of the abscess is discharged. The inflammation around the abscess will now subside, as the pressure is taken off and normal circulation is restored. The walls of the abscess unite and the parts are restored to health. This is nature's surgery without any antiseptics. I can hardly conceive that every particle of pus is evacuated in this manner, yet the wound heals kindly, and I believe that the remaining pus is absorbed either directly as such, or, having gone through some chemical change, is absorbed by the parts which lately secreted it, and that such absorption is safe, healthy, and natural.

Take another example: A person is burned over quite a large surface, sufficient to cause the true skin to die and slough off. Soon after the injury nature commences repair by casting off the dead tissues, and under it will soon be found the parts liberally bathed in pus. Has nature made a mistake and covered the wound with a poison? No! Under this covering of horrid pus, so much feared by modern pathologists, will be seen healthy granulations which when they have filled up, the lost tissue commences forming new skin. Of course we have no direct evidence that any of this pus on an open wound is absorbed, yet we do have abundant evidence that it is not only harmless but absolutely healthy and the normal first covering of all open wounds. And I see no good reason why at least some of its elements may not be absorbed and converted into new tissue or expelled through the many excretory organs without any injury to health. Again, I have often seen small fluctuating tumors which had all the appearance of containing pus disappear entirely without any apparent discharge or constitutional disturbance.

Among many cases which have led me to believe that pus pure and simple forming in or on healthy individuals can be taken up in some manner and utilized in the living organism are these:

I had a case of injury of knee-joint caused by a fall. The patient was a young man of good health and habits previous to the injury. The knee became enormously swollen, inflamed, and painful, and I determined to open it, although at that time—some thirty-five years ago—it was almost malpractice to open a serous sac, especially the knee-joint. I made a valvular incision with a common thumb-lancet and carefully evacuated about four ounces of thick pus. I used no pressure or syringe to wash or squeeze out the whole of the matter. I allowed the skin to cover the opening and dressed the leg on a double inclined splint and with evaporating lotions. The wound never discharged any more pus, the inflammation gradually subsided, and the man had a useful knee-joint. I have no doubt but some of the pus was absorbed.

I will give a brief statement of one more case that I think illustrates the fact that pus is sometimes absorbed. I was called some two years ago to see a boy about ten years of age, and of a good constitution. About two weeks before I was called he came home from school in a severe chill. His mother put him to bed and "gave him a sweat," thinking it was nothing but a bad cold, although the boy had a severe cough which was very constant and without any expectoration. The family (who were quite afraid of the doctor's bill) neglected calling a physician, and when I saw the boy he had a pulse of 130, respiration 45, and a temperature of 104° F., with one lung impervious to air, the intercostal spaces bulging, in fact all the usual symptoms of a large collection of fluid in the pleural cavity. This patient was aspirated and about four ounces of thick pus removed from the pleural cavity. The patient being very weak and showing signs of collapse, the aspirating needle was removed, although pus continued to flow, and it was expected that the operation would have to be repeated in the near future. But very much to our surprise the lung again inflated, the constitutional and local symptoms all gradually disappeared, and the boy to-day seems perfectly well, with an apparent thickening of the pleura and a slight friction sound. It does not seem probable that all the pus could have been removed, yet no blood-poisoning, and in fact no trace of the fluid, now remains. I think it must have been absorbed.

With an experience of over forty years I do not now remember a single case occurring in a healthy person where I could trace any blood-poisoning from the presence of pus alone. Only in the debilitated, broken-down constitutions, where the slightest cause would destroy vitality, have I seen any bad effects of pus, except the exhaustion which comes from the waste of tissue from the excessive secretion. Even in lumbar and psoas abscess, which generally terminates fatally, I have never seen a case of blood-poisoning. Therefore, from these and many other clinical facts, I have come to these conclusions: That pus is sometimes absorbed into the system; that if not absorbed it is not of itself a dangerous product, and only becomes so when mingled with dead and decaying tissue, or is so excessive as to exhaust the patient; that all pus-cavities occurring in healthy subjects which have been fairly well evacuated, sufficient to remove all pressure, and are so situated as to allow the walls of the abscess to be in apposition, will take on a healthy action and result in a perfect cure; and that the danger of blood poisoning from the presence of pus has been greatly exaggerated by our modern pathologists.

A CASE OF MYXŒDEMA.

By MARIA M. VINTON, M.D.

NEW YORK.

A. I——, aged forty five; married twenty-seven years, was first seen at the Dispensary of the Woman's Medical College of the New York Infirmary in May, 1890, and continued under observation for about one year. She has had eight children, one died in infancy, the other seven are living and healthy, and show no signs of myxœdema as far as can be ascertained. Two daughters who have been seen, are slim and active. The patient's mother was never stout. She died of "lung trouble." Her father is living and well. He is stout, but not myxœdematous. There are no cases of the disease in the family of either parent, or in the present generation.

The patient has always been very healthy, never con-

fined to the bed, except at the times of the birth of her children. Sixteen years ago, after child-birth, she grew very stout and heavy, and "lost all her strength." Her friends told her that she had dropsy, but her physician contradicted this statement, telling her that it was not healthy fat, but giving no name to the disease. This condition lasted for about two months. The stoutness gradually disappeared and her strength returned. Since that time the skin of her hands has been very dry. Whether this was a transient attack of myxœdema, it is impossible to say, but such cases have been reported. She remained well up to seven years ago, when the menopause occurred at thirty-eight years, without any marked disturbances. At this time she began to feel as if her body was too heavy for her legs to carry, and her movements became slow. At the same time she noticed a sensation of coldness about the back and hips. The symptoms increased very gradually up to four years ago, when her house and her husband's store were burned to the ground, the family escaping in their night-clothes and saving nothing. This shock and the consequent worry, with their subsequent removal to America, seemed to cause a more rapid increase in her symptoms. Four years ago, that is three years after the menopause, she began to have hemorrhages from the uterus. Since then she has had six or more. One occurred in May, 1891; not repeated for about four months, and they then recurred at intervals of about one month. She has had no hemorrhages from the nose or mouth or any other part of the body, and no purpura. She has occasional attacks of palpitation on exertion. Her bowels are very constipated, and she has had lately several attacks of crampy pain followed by diarrhœa and clay-colored stools, but no jaundice.

About two years ago her teeth loosened and fell out without pain, leaving the gums spongy. Her hair has also been falling out, particularly during the last two years.

Present Condition.—Her face is remarkably broad, especially over the cheek-bones; the nose broad, thick, and flattened. The eyelids are puffy, and, as she says, "her eyes have grown small," that is, less of the sclerotic is seen on account of the increase of tissue in the lids. The scalp is thinly covered with hair, so that she has to wear considerable false hair to conceal it. Her lips are thick and feel stiff to the patient, as do the eyelids. In talking she forms her words slowly, but thinks the difficulty is due to her loss of teeth. The tongue is large and flat, but she feels no difficulty in moving it, though she talks as if her mouth were full. The expression of the face is stupid and placid. The skin has a waxy, smooth look, in marked contrast to the bright, circumscribed flush over the cheek-bones. The neck is very large, especially about the ears, and she has a full double chin. The thyroid gland cannot be felt. The arms and legs are very large and the tissues elastic and firm to the touch, and there is no pitting on pressure. She says her feet and hands are not increased in size, and that she wears no larger size of gloves or shoes than formerly. Three years ago she thinks her legs were much larger than they are now.

The bust is very full. The heart-sounds are feeble and the heart cannot be mapped out, nor the apex-beat felt, on account of the masses of thickened tissues in the mammary glands and walls of the chest. The lung-sounds are normal. The abdomen is large and pendulous. She is obliged to wear an abdominal belt, and says that in walking "her stomach seems to pull her forward." The abdominal walls are very thick and can be gathered up in masses between the hands. The liver is of normal size. The small and large intestines are tympanitic, and somewhat tender on deep pressure, following a late attack of pain and diarrhœa.

The temperature is 97.8° F.; pulse, 82; urine, specific gravity, 1.017, contains no albumin or casts. Her speech is very deliberate, as well as her mental action. She answers questions intelligently after a little thought, and gives dates correctly. She says her memory is poor, and she cannot carry on her household affairs on that account. She cannot make change well in buying at the stores, and never goes out alone. She does not read much, but does her family mending. She is very nervous and emotional, crying at nearly every visit to the clinic. She moves very slowly and with evident difficulty. She complains greatly of a sensation of coldness and dull pain in the lumbar region. This alternates with burning over the base of the spine and right arm, but the cold predominates. She has no anæsthesia, no other paræsthesiæ, and no special sense troubles. Her hands are very cold and purplish in winter, particularly the nails, which are well formed. The skin is dry, but not scaly.

This case presents all the typical symptoms of this rare and interesting disease. The appearance is very characteristic, and would attract the notice of even a casual observer.

Up to 1888, when Drs. Hun and Prudden published a very interesting series of papers giving an account of four cases, with two autopsies, there has been reported one hundred and fifty cases of myxœdema. Since then a considerable number of additional cases have been reported. Unfortunately there are few autopsies, but the results of such examinations as have been made go to show that the increase in tissue is not due to mucous tissue, and that the name myxœdema is a misnomer. The thyroid seems to be uniformly absent or atrophied, showing an increase in the connective tissue, and atrophy of the gland structure proper.

COMPLETE LACERATION OF THE PERINEUM WITHOUT RISE OF TEMPERATURE—UNION BY FIRST INTENTION, AND RAPID RECOVERY.

By L. W. ARNOLD, M.D.,

FLORENCE, ALA.

In the Medical Record of September 12 and December 19, 1891, I notice articles of Drs. Boxhall and C. S. Scofield, in regard to rupture of the perineum without rise of temperature. I beg leave to report a similar case in support of said articles. On December 14th I was called to the country with Dr. Brunlett, my colleague, to deliver one Mrs. P——, a primipara, thirty-eight years of age. The physician in attendance reported forty-eight hours of labor pain, followed by forty-eight hours of uterine inertia. On examination we found a very contracted pelvis and rigid perineum. Contents of uterus in a semi-decomposed state, judging from the offensive odor that penetrated the atmosphere of the lying-in room. We at once decided to deliver with forceps, well knowing that we would have a lacerated perineum to contend with. The head of the child was unusually large. After the child was delivered I found complete laceration of both walls—intestinal as well as vaginal. The rupture was at least three inches long, presenting a rather ragged, ugly-looking wound. We thereupon concluded to irrigate the uterus and vagina with one to two thousand solution of bichloride, which we did, having the solution almost scalding hot. After thoroughly emptying the uterus and vagina of all débris, I took seven stitches, three in the intestinal and four in the vaginal walls, looking well to thorough approximation of the lacerated surfaces; applied an abdominal compress, and then a napkin was pinned, holding firmly to the perineum a pad consisting of a thick roll of absorbent cotton, wrung out of a strong bichloride solution. On returning the following day, I found the temperature 99° F., pulse 110. Removed bandages, and irrigated the vagina with four gallons of a hot solution of bichloride. I ordered vagina to be irrigated morning, noon, and night with a bichloride solution as hot as could be borne. The patient at this date, December 28th, is doing well. I have but recently dismissed a somewhat similar case, but in that instance

used Labarraque's solution of chlorinated soda, the last filling the requirements equally as well as the bichloride. Good drainage and thorough irrigation mean cleaning of the parts, and if kept clean, the patients will all recover. Ninety-nine out of one hundred cases of septic infection are due to the neglect of the attending physician or nurse. I always, in every instance, order pads to be applied to the vulva. This insures perfect cleanliness, gives good support to the perineum, prevents fetor, and prevents the secretions from saturating bed-clothes.

TUMOR OF VOCAL CORD—REMOVAL.

By EDWIN CARSON, M.D.,

SAN DIEGO, CAL.

Mr. G. L. H——, aged about sixty-three. Previous history good, with the exception of an attack of influenza two years ago. I saw the patient for the first time about the middle of last September, when he presented himself for the relief of some throat trouble involving the loss of his voice.

Present condition, fairly developed and nourished; general health, good; voice consists of a hoarse, stridulous, half whispering sound. The patient states that he was treated in Washington one year ago, but the endo-laryngeal growth was not discovered at that time. He had been in the habit of using his voice a good deal in public speaking during the past ten years, up to a year ago, when he had to give it up on account of aphonia. He dates the present trouble from an attack of the grip, which he experienced two years ago. On examination with the laryngoscope, a small, smooth, rounded, reddish growth, oval in shape, and sessile, about half the size of a white navy bean, was seen to spring from the edge of the anterior half of the left vocal cord. During an attempt at phonation, the neoplasm was brought into contact with the edge of the right cord, which curved around it, leaving a short buttonhole opening in front and a longer one behind, thus preventing the closure of the glottis. The other portions of the larynx were normal except the mucous lining, which showed slight catarrhal congestion. The throat not being particularly sensitive, it yielded to the education imparted to it by the frequent introduction of an instrument, so that in ten days a tolerance of some manipulation had been attained. The throat discipline was conducted under the influence and aid of a four per cent. solution of cocaine spray, but on account of a high-arched tongue, and a low-vaulted palate, the larynx was not easy of access. I first used a forceps of $3\frac{1}{2}$-inches length of downward curve, but found it would not reach the cords. I then sent a special order to a New York maker for a pair of $3\frac{7}{8}$-inches down curve, lateral opening, and serrated edge jaws. With this I succeeded in removing a small part of the growth, with immediate improvement of the voice. But desiring the down curve made even a little longer, I took the instrument to a local "tinker," and he managed to break one of the blades, which was badly mended, and I found he had given me a down curve of $4\frac{1}{2}$ inches. I introduced it, however, with difficulty, but it was so out of shape as to be useless, and I abandoned it and ordered another, this time with cutting edges. With this I cut away the growth, little at a time, at the last sitting, except a small portion on the anterior extremity of the cord, almost at its attachment to the thyroid cartilage, which was very difficult to reach on account of being so far forward. The operation was followed by great improvement in the voice, but as the gentleman had to go East the next day, any further efforts had to be deferred until his return.

For about a century and a half intra-laryngeal growths have been diagnosed, but prior to 1859, when Czermak introduced the laryngoscope, it was done by the physical signs, and probing with the finger. By the use of the mirrors and reflected light, the laryngeal cavity admits of complete and ready inspection. Without submitting any of the pieces of the removed growth to microscopical tests, I made a diagnosis of fibroma, first, because of its slow growth, about two years, and on account of its smooth, rounded appearance, having nothing of the excrescence that characterizes the papilloma.

Endo laryngeal neoplasms are not frequently met with, but when they do occur, the authorities agree that the vocal cords are their most favored sites; and of all the growths that invade the larynx, the papillomata are the most frequent, constituting about three-fourths of all such cases. According to Mackenzie, about ten per cent. of all are fibromata. While writing the last of these notes, the patient's wife came in and reported that her husband's voice had improved and grown much stronger since his departure for the East. I have lately had a letter from the patient in which he says, "My voice is entirely restored."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 20, 1892.

	Cases.	Deaths.
Typhus fever	25	2
Typhoid fever	14	2
Scarlet fever	223	39
Cerebro-spinal meningitis	0	0
Measles	209	13
Diphtheria	141	26
Small-pox	10	2
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

The Diagnosis of Gastric Ulcer.—In the course of a recent discussion on ulcer of the stomach in one of the London medical societies, Dr. Routh said that electricity assisted in the diagnosis of gastric ulcers; if there were really an ulcer the pain would be intensified on passing the constant current through the painful spot, whereas if no ulcer existed the current would afford relief.

The Universities of the World.—There are 147 universities in the world, of which the largest is in Paris, with 9,215 students; the next in Vienna, with 6,220; the third in Berlin, with 5,527. The smallest is a branch of Durham University, Fourah Bay College, in Sierra Leone, with twelve students and five professors.

Human Mortality.—The annual mortality of the entire human race amounts, roughly speaking, according to a French medical journal, to 33,000,000 of persons. This makes the average deaths per day over 91,000, being at the rate of 3,730 an hour, or 62 people every minute of the day and night the year round. A fourth of the race die before completing their eighth year, and one-half before the end of the seventeenth year; but the average duration of life is about thirty-eight years. Not more than one person in a hundred thousand lives to be a hundred.—*New York Sun.*

The Health of the Small Boy again Threatened.—An industry of great promise in Japan, for purposes of export, is the manufacture of cigarettes. Japanese tobacco, though not suitable for pipes or cigars, makes excellent cigarettes, pronounced by the majority of smokers to be only a little inferior to cigarettes made with Turkish tobacco, and the advantage is very distinctly on the side of the Japanese article in respect of cheapness, its ratio of price to that of the Turkish being as three to five, approximately.—*Japanese Mail.*

PRESENT PROBLEMS IN EVOLUTION AND HEREDITY.

THE CARTWRIGHT LECTURES FOR 1892.

(Continued from p. 204.)

LECTURE II.

THE DIFFICULTIES IN THE HEREDITY THEORY.

"Nur muss ich nochmals betonen, dass nach meiner Auffassung der Anfang einer neuen Reihe erblicher Abweichungen, also auch der Eintritt einer neuen Art ohne eine vorausgegangene erworbene Abweichung undenkbar ist."—VIRCHOW.

State of Opinion.—The above quotation from one of the most eminent authorities of our times represents the unshaken conviction of a very large class upon one side of the question of transmission of acquired characters, which is met by equally firm conviction upon the other side.

Herbert Spencer, whose entire system of biology, psychology, and ethics is based upon such transmission says: "I will only add that, considering the width and depth of the effects which acceptance of one or other of these hypotheses must have on our views of Life, Mind, Morals, and Politics, the question Which of them is true? demands, beyond all other questions whatever, the attention of scientific men."[1] This shows that Spencer considers the matter still *sub judice*, and lest you may think I am bringing before you an issue in which learning and experience are ranged against ignorance and prejudice, I have taken some pains, by correspondence with a number of friends abroad, to learn the present state of opinion. The two leading English and French authorities upon this subject express themselves doubtfully.

Galton's mind is still wavering, as in his work of 1889:[2] "I am unprepared to say more than a few words on the obscure, unsettled, and much discussed subject of the possibility of transmitting acquired faculties. . . . There is very little direct evidence of its influence in the course of a single generation, if the phrase of Acquired Faculties is used in perfect strictness and all inheritance is excluded that could be referred to some form of Natural Selection, or of Infection before birth, or of peculiarities of Nurture and Rearing."

Ribot, although in the centre of the French Lamarckians, says: "Notwithstanding these facts the transmission of acquired modifications appears to be very limited, even when occurring in both of the parents."

Excepting from Kölliker; His, the Leipsic anatomist; Pflüger, the physiologist; Ziegler, in pathology; and De Vries, in botany, Weismann has not found much sympathy from his own countrymen in his opinion "that acquired characters cannot be transmitted; . . . that there are no proofs of such transmission, that its occurrence is theoretically improbable, and that we must attempt to explain the transformation of species without its aid."[3] Besides Virchow[4] and Eimer,[5] Haeckel has expressed himself strongly against Weismann. My colleague, Professor Wilson, writes me (Munich, December 31, 1891) that, while Weismann's modified theories as to the phenomena in the reproductive cells are pretty generally accepted, Hertwig, Hofer, Paully, Boveri, and others are pronounced advocates of the acquired-character-transmission theory.

In Paris, Brown-Séquard, who was among the first to test this problem experimentally by observing the inheritance of the effects of nerve lesions; his assistant, Dupuy, Giard, Duval, Blanchard, and others are on the affirmative, or Lamarckian side.

Physiologists generally have fought shy of the question, although I think in the end they will be forced to take it up with the morphologists, and give us the physio-morphological theory of heredity of the future. Professor Michael Foster, of Cambridge, and Professor Burdon-Sanderson, of Oxford, both write me that the question has hardly come into the physiological stage of inquiry at all. Yet in England Weismann has found his strongest supporters among some of the naturalists: Wallace, Lankester, Thiselton Dyer, Meldola, Poulton, Howes, and others; while, excepting Windle, the anatomists, including Mivart and Lawson Tait, with Sir William Turner as the most prominent, are all Lamarckians. Huxley, Romanes, and Flower are said to be doubtful. In this country the opinion of naturalists is directly the outgrowth of the class of studies in which each happens to be engaged. So far as I know every vertebrate and invertebrate palæontologist is a Lamarckian,[1] for in this field all evolution seems to follow the lines of inherited use and disuse; most of those engaged upon invertebrate zoölogy incline to follow Weismann. I have conversed upon this subject with many physicians, and find that without exception the transmission of acquired characters is an accepted fact among the profession.

Exact Statement of the Problem.—It is important at the outset to state most clearly what is and what is not involved in this discussion. Weismann[2] does not claim that the reproductive or germ-cells are unirfluenced by habit; on the other hand, he admits that most important modifications in these cells may and do result from changes of food, climate, from healthy or unhealthy conditions of the body; also from infectious disease, where it is quite as possible that the microbes may enter the reproductive cells as any other cells of the body; from alcoholism, where the normal molecular action of the protoplasm of the germ-cells may be disturbed, resulting in abnormal development, and there are some very interesting experiments which I shall cite on this point; from some nervous disorders which profoundly modify cell-function in all the tissues; in other words, *ovum sanum in corpore sano*. But to accept all this, and even to include all our rapidly increasing knowledge of the direct relation between such phenomena as production of deformities and determination of sex, and the influences of environment upon the ovum; or the influences of the mother upon the fœtus—this is all aside from the real question at issue.

It may be stated thus: Given *G*, the ova and spermatozoa, the germ cells or material vehicles of hereditary characters; *S*, the body or somatic cells of all the other tissues conveying the hereditary characters of nerve, muscle, and bone; *V*, the variations in these body-cells "acquired" during lifetime; given these factors, the real question is: Do influences at work producing variations in certain body-cells of the parent so affect the germ-

cells of the parent that they reappear in corresponding body-cells of the offspring? To take a concrete case, will the increased use of the cells of the extensor indicis muscle in the parent so stimulate that portion of the germ-cells which represents this muscle that the increment of growth will in any degree reappear in the offspring?

This is what is required of heredity upon the Lamarckian hypothesis, and I think you will see at once that while this hypothesis simplifies the problem of evolution it in a corresponding degree renders more difficult the problem of heredity—for we have not the first ray of knowledge of what such a process involves. There is no quality more essential to scientific progress than common honesty; if we take a position let us face all its consequences; the more we reflect upon it, the more serious the Lamarckian position becomes.

In the present lecture let us first briefly review the progress of the science of heredity which has led up to the present discussion. Second, Let us examine the evidence for and against the Lamarckian theory, and inquire how far natural selection can explain all the facts of evolution. Third, Let us examine the evidence for such a continuous relation between the body-cells and germ-cells, as must exist if the Lamarckian theory is the true one.

History of the Heredity Theory.—In a valuable summary of the past theories of heredity[1] J. A. Thomson distinguishes three general problems, which are often confused. 1st. What characters distinguish the germ-cells from other cells of the body? 2d. How do the germ-cells derive these distinguishing characters? 3d. How shall we interpret "particulate" inheritance, or the reappearance of single peculiarities in the offspring?

The various theories may be grouped under two heads, "Pangenesis of Germ-cells" and "Continuity of Germ-cells," according to the dominating idea in each.

1. *Pangenesis.*—The idea pervading pangenesis was first expressed by Democritus that the "seed" of animals was derived by contributions of material particles from all parts of the bodies of both sexes, and that like parts produced like. Two thousand years later, Buffon revived this conception of heredity in his "molecules organiques." In 1864 Herbert Spencer suggested the existence of "physiological units," derived from the body-cells of the parent, forming the germ-cells and then developing into the body cells of the offspring.

It is interesting to note the course of Darwin's thought upon this matter in his published works and in his "Life and Letters." He was at first strongly opposed to the views upon evolution advanced by Buffon, by Erasmus Darwin, his grandfather, expanded by Lamarck, and now known as Lamarckian. But gradually becoming convinced that his own theory of natural selection could not account for all the facts of evolution, he unconsciously became a strong advocate of Lamarck's theory, and contributed to it a feature which Lamarck had entirely omitted, namely, a theory of heredity expressly designed to explain the transmission of acquired characters. Darwin's[2] "provisional hypothesis of pangenesis" postulated a material connection between the body-cells and germ-cells by the circulation of minute buds from each cell; each body-cell throws off a "gemmule" containing its characteristics; these gemmules multiply and become especially concentrated in the germ-cells; in the latter they unite with others like themselves; in course of development they grow into cells like those from which they were originally given off. (See Diagram II.)

Galton,[3] who has always been doubtful in regard to use-inheritance, while advancing a theory of "continuity," partly approved Darwin's pangenesis idea in the cautious statement: "Each cell may throw off a few germs that find their way into the circulation and thereby have a chance of entering the germ-cells." At the same time Galton contributed very important experimental disproof of the existence of "gemmules," and, in fact, of the popular idea of the circulation of hereditary characters in the blood, by a series of careful experiments upon the transfusion of blood in rabbits; he found that the blood did not convey with it even the slightest tendency to transfer normal characteristics from one variety to another.

Professor Brooks,[1] of the Johns Hopkins University, then contributed an original modification of pangenesis in which the functions of the ova and spermatozoa were sharply differentiated. (1) He regarded the ovum as a cell especially designed as a storehouse of hereditary characteristics, each characteristic being represented by material particles of some kind; thus hereditary characters were handed down by simple cell division, each fertilized ovum giving rise to the body-cells in which its hereditary characters were manifested and to new ova in which these characters were conserved for the next generation (this portion of Brooks's theory is very similar to Galton's and Weismann's). (2) The body-cells have the power of throwing off "gemmules," but this is exercised mainly or exclusively when its normal functions are disturbed, as in metatrophic exercise or under change of environment. (3) These gemmules may enter the ovum, but the spermatozoan is their main centre. According to this view the female cell is rather conservative and the male cell progressive; the union of these cells produces variability in the offspring, exhibited especially in the regions of the offspring corresponding to the regions of functional disturbance in the parent. This hypothesis was well considered, and while that feature of it which distinguishes the male and female germ-cells as different in kind has been disproved, and the whole conception of gemmules is now abandoned, the fact still remains that we shall nevertheless be obliged to offer some hypothesis to explain the facts disregarded by Weismann for which Brooks provides in his theory of the causes of variation.

2. *Continuity of Germ-cells.*—The central idea here is an outgrowth of our more modern knowledge of embryogenesis and histogenesis, and is, therefore, comparatively recent; it is that of a fundamental distinction between the "germ-cells," as continuous and belonging to the race, and the "body-cells," as belonging to the individual. Weismann has refined and elaborated this idea, but it was not original with him.

Richard Owen,[2] in 1849, Haeckel,[3] in 1866, Rauber,[4] in 1879, in turn dwelt upon the distinction which Dr. Jaeger, now of manufacturing fame, first clearly stated:

"Through a great series of generations the germinal protoplasm retains its specific properties, dividing in every reproduction into an ontogenetic portion, out of which the individual is built up, and a phylogenetic portion, which is reserved to form the reproductive material of the mature offspring. This reservation of the phylogenetic material I described as the continuity of the germ protoplasm. . . . Encapsuled in the ontogenetic material the phylogenetic protoplasm is sheltered from external influences, and retains its specific and embryonic characters." The latter idea has, under Weismann, been expanded into the theory of isolation of the germ-cells.

Galton introduced the term "stirp" to express the sum total of hereditary organic units contained in the fertilized ovum. His conception of heredity was derived from the study of man, and he supported the idea of continuity in the germ-cells in order to account for the law of transmission of "latent" characters; it is evident from this law that only a part of the organic units of the "stirp" become "patent" in the individual body; some are retained latent in the germ-cells, and become patent only in the next or some succeeding generation. For example, the genius for natural science was "patent"

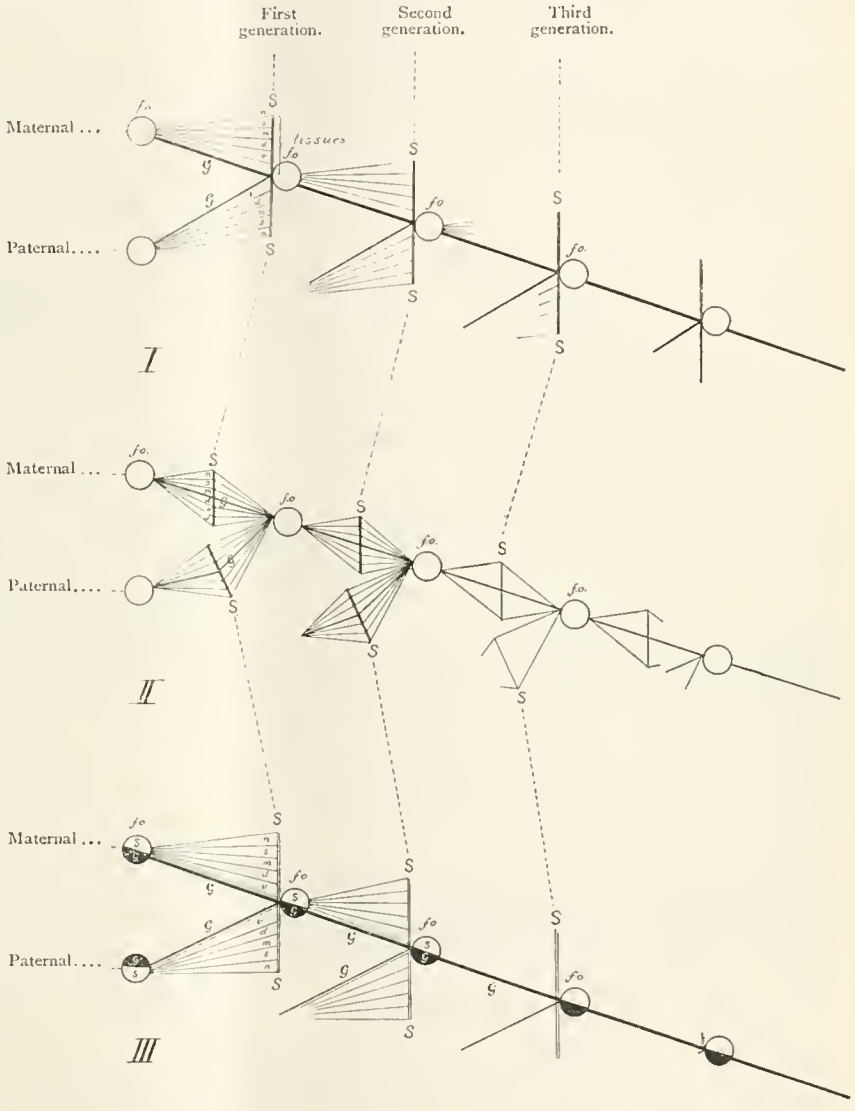
in Erasmus Darwin, grandfather of the great naturalist, it] was "latent" in his son, and reappeared intensified in his grandson, Charles Darwin. I have elsewhere[1] summed up as follows Galton's general results, which so remarkably strengthen the "continuity" idea: We are made up, bit by bit, of inherited structures, like a new building, composed of fragments of an old one, one element from this progenitor, another from that, although such elements are usually transmitted in groups. The hereditary congenital constitution thus made up is far stronger than the influences of environment and habit upon it. A large portion of our heritage is unused, for we transmit peculiarities we ourselves do not exhibit. The contributions from each ancestor can be estimated in numerical proportions, which have been exactly determined from statistics of stature in the English race; thus the contributions from the "patent" stature of the two parents together constitute one-half; while the contributions by "latent" heritage from the grandparents constitute one-sixteenth, etc. One of the most important demonstrations by Galton, is the *law of regression;* this is the factor of stability in race type which acts as gravitation does upon the pendulum; if an individual or a family swing far from the average characteristics of their race, and display exceptional physical or mental qualities, the principle of regression in heredity tends to draw their offspring back to the average.

Now how shall we distinguish regression from reversion? Very clearly, I think; *regression* is the short pull which tends to draw every variation and the individual as a whole back to the contemporary typical form, while *reversion* is the long pull which draws the typical form of one generation back to the typical form of a very much earlier generation. These forces are evidently akin, and in the shades of transition from one type to another we would undoubtedly find a constant diminution numerically in the recurrence of characters of the older type, and thus "regression" would pass insensibly into "reversion."

Weismann has carried the idea of continuity to its extreme in his simple and beautiful theory of heredity, which is founded upon the postulate that there is a distinct form of protoplasm, with definite chemical and molecular properties, set apart as the vehicle of inheritance; this is the *germ-plasm*, *G*, quite separate from the protoplasm of the body cells or *somatoplasm*, *S*. Congenital characters arising in the germ cells are called *blastogenetic*, while acquired characters arising in the body-cells are *somatogenetic*.

To clearly understand this view, let us follow the history of the fertilized ovum in the formation of the embryo. It first divides into somatoplasm and germ-plasm (see Diagram III.). the former supplies all the tissues of the body—*n*, *s*, *m*, *d*, *v*, nervous, muscular, vascular, digestive, etc.—with their quota of hereditary structure; the residual germ-plasm is kept distinct throughout the early process of embryonic cell division until it enters into the formation of the nuclei of the reproductive cells, the ova or spermatozoa. Here it is isolated from changes of function in the somatoplasm, and in common with all other protoplasm is capable of unlimited growth by cell division without loss or deterioration of its past store of hereditary properties; these properties are lodged in the nucleus of each ovum and spermatozoan, and these two cells, although widely different in external accessory structure (because they have to play an active and passive part in the act of conjugation), are exactly the same in their essential molecular structure, and the ancestral characters they convey differ only because they come along two different lines of descent. When these cells unite they carry the germ-plasm into the body of another individual. Thus the somatoplasm of each individual dies, while the germ-plasm is immortal; it simply shifts its abode from one generation to another; it constitutes the chain from which the individuals are mere offshoots. Thus the germ-plasm of man is continuous with that of all ancestors in his line of descent, and we have an explanation of the early stages observed in development in which the human embryo passes through a succession of metamorphoses resembling the adult forms of lower types.

In order to emphasize, as it were, the passage of the germ-plasm from one generation to another without de-



f.o., fertilized ovum or *embryo*, containing maternal and paternal characteristics; *S*, soma, or adult body, containing *n*, *s*, *m*, *d*, *v*, *somatic cells* of the various tissues; and *G*, *germ-cells* of the reproductive glands.

I. Histogenesis.—Showing the successive rise *G*, and union *f.o.* of the maternal and paternal germ-cells by direct histogenesis.

II. Pangenesis.—Showing the tissues of the body *S*, contributing to the germ-cells *G*, so that each *f.o.* is composed of elements from both the somatic and germ-cells.

III. Continuity.—Showing the division of the embryo, *f.o.*, into somatoplasm, *s* (from which arise the body-cells), and germ-plasm, *G* (which passes direct to the germ-cells), establishing a direct continuity.

[1] Atlantic Monthly, March, 1891, p. 359.

terioration in its marvellous hereditary powers, Weismann added the idea of its *isolation*. Not only does he repudiate the pangenesis notion of increment of germ-plasm by addition of gemmules, but he believes that it is unaffected by any of the normal changes in the somatic or body cells. As this continuity and isolation would render impossible the transmission of characters acquired by the somatoplasm, Weismann began to examine the evidence for such transmission, and coming to the conclusion that it was insufficient, in his notable essay on "Heredity," in 1883, he boldly attacked the whole Lamarckian theory and has continued to do so in all his subsequent essays.

Being forced to explain evolution without this factor, he claimed that variation in the germ-plasm was constantly arising by the union of plasmata from different lines of descent in fertilization, and that these variations are constantly being acted upon by Natural Selection to produce new types. He thus revived Darwin's earlier views of evolution, and this in part explains his strong support by English naturalists.

It will be seen at once that there are a number of distinct questions involved.

The matter of first importance in life is *the repetition and preservation of type*, the principle which insures the unerring accuracy and precision with which complex organs are built up from the germ-cells; the force of regression and the more remote forces of reversion all work in this conservative direction; the theory of the preservation of these forces in a specific and continuous form of protoplasm is by far the most plausible we can offer at present.

The matter of second importance, but equally vital to the preservation of races, in the long run, is *the formation of new types* adapted to new circumstances of life. I shall now attempt to show that the facts of evolution, while not inconsistent with the idea of continuity of the germ-plasm, are wholly at variance with the idea of its independence, separation, or isolation from the functions of the body. This can be done by proving, first, that the theory of evolution solely by natural selection of chance favorable variations in the germ-plasm is inadequate; second, that the inheritance of definite changes in the somatic cells is also necessary to explain evolution, and therefore there must exist some form of force or matter which connects the activities of the somatoplasm with those of the germ-plasm.

In the following table are placed some of the facts of human evolution which we have observed in the first lecture, and as they are part of inheritance, they also constitute the main external phenomena of heredity:

Phenomena of Heredity.

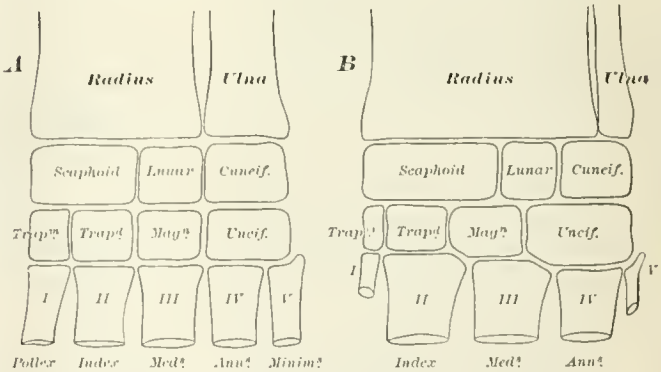
Conservative (toward past type).	*Neutral.*	*Progressive* (toward future type).
a. Repetition of parental type.	Fortuitous	*a.* Definite Variation in single characters, by accumulation =.
	and	
b. Regression (in many characters) to contemporary race type.	Indefinite	*b.* Definite Variation in many characters (from contemporary race type).
c. Reversion (mainly in single characters) to past race type.	Variability.	

What are the causes of these various phenomena?

Factors of Evolution.—The term "kinetogenesis" has been applied to the modern form of the Lamarckian theory, for it is an application of kinetic or mechanical principles to the origin of all structures such as teeth, bone, and muscle. It would be fatal to this theory if it could be shown that the changes taking place in course of a normal individual life, under the laws of use and disuse, are inadaptive, or do not correspond to those observed in the evolution of the race.

The Relative Growth of Organs.—Ball,[1] in his long argument against Lamarckianism, claims that such is the case, and that use-inheritance would be an actual evil: "Bones would often be modified disastrously. Thus the condyle of the human jaw would become larger than the body of the jaw, because as the fulcrum of the lever it receives more pressure. Some organs (like the heart, which is always at work) would become inconveniently or unnecessarily large. Other absolutely indispensable organs which are comparatively passive or are very seldom used would dwindle until their weakness caused the ruin of the individual or the extinction of the species." He later cites from Darwin[2] the "Report of the United States Commission upon the Soldiers and Sailors of the Late War," that the longer legs and shorter arms of the sailors are the reverse of what should result from the decreased use of the legs in walking and increased use of the arms in pulling. A little reflection on Mr. Ball's part would have spared us this crude objection, for whatever difficulties may arise from theoretical speculation as to the laws of growth, or from statistics, the fact remains that activity must increase adaptation in every part of the organism; otherwise the runner and the trotting horse should be kept off the track to increase their speed, the pianist should employ as little finger-exercise as possible. If the growth tendencies in single organs are transmitted, it is evident that the adaptive adjustments between these tendencies will also be transmitted.

The Feet.—In point of mechanical adaptation, man, with the single exception of his thumb and forearm, has not progressed beyond the most primitive eocene quadruped. The laws of evolution of the foot in the ungulate or hoofed animals, which have been especially studied by Kowalevsky, Ryder, Cope, and myself, affords a conclusive demonstration that the skeletal changes in the individual coincide with those which will mark the evolution of the race. In the earliest ungulates the carpals and tarsals are disposed, as in man, directly above each other, with serial joints, as in *A*; in the course of evolution all these joints became interlocking, as in *B*, thus



PRIMITIVE UNGULATE FOOT.—Lines of vertical cleavage on either side of the middle toe, III. Spreading of toes would cause separation of the carpals.

RECENT UNGULATE FOOT.—No lines of vertical cleavage. All joints broken by enlargement of scaphoid, unciform, and radius, the bones receiving greatest impact in walking. Lateral toes, I, V., degenerate.

producing an alternation of joints and surfaces similar to those which give strength to masonry. In studying these facts Cope[3] reached a certain theory as to the motion of the foot and leg in locomotion. In trying to apply this, I found it could not be harmonized with all the facts, and I worked out an entirely different theory.[4] This I found subsequently coincided exactly with the results previously obtained by Muybridge, by the aid of instantaneous photographs, and summarized by Professor Harrison Allen, of the University of Pennsylvania.[5]

The monodactylism of the horse was attained by the

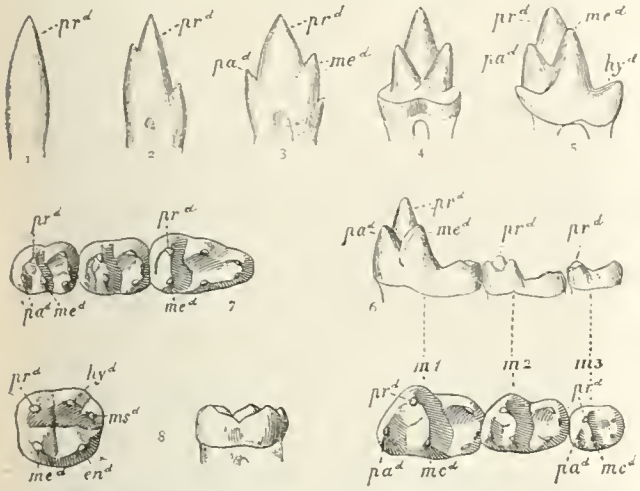
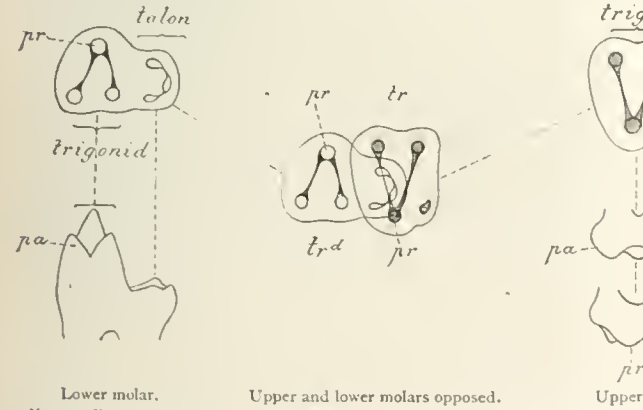
atrophy of the lateral toes, and concentration of the major axis of body-weight and strain upon the middle finger and toe. Man is also tending toward monodactylism in the foot by the establishment of the major axis through the large toe and atrophy of the outer toes. The present atrophy of our small toe is as good a parallel as we can find of the changes which were occurring in the eocene period among the ancestors of the horse.



Evolution of the Cusps of the Human Lower Molar.—*pr^d*, protoconid (anterior buccal cusp); *pa^d*, paraconid; *me^d*, metaconid (anterior lingual cusp); *hy^d*, hypoconid (posterior buccal); *en^d*, entoconid (posterior lingual cusp); *ms^d*, mesoconulid (intermediate cusp). Fig. 1.—Reptilian stage. Figs. 2–5.—Mesozoic mammals, first lower molars showing rise of ancestral cusps. Fig. 6.—Eocene carnivore (*Miacis*), showing how the low tubercular crown *m3* is derived from the high crown *m1*. Fig. 7.—Eocene monkey (*Anaptomorphus*), showing how the primitive anterior lingual cusp, *pa^d*, disappears. Fig. 8.—Human first molar with its ancestral cusps.

The Teeth.—But how about the teeth, in which there is an absolute loss of tissue in consequence of use? This is another objection raised by Ball, Poulton, and others which disappears upon examination.

The dental tissues, while the hardest in the body, and, unlike bone, incapable of self-repair, are not only both living and sensitive, but, to a very limited degree, plastic and capable of change of form. *Ex hypothesi*, it is not the growth, but the reaction tendency which produces the growth, which is transmitted. The evolution of the teeth, therefore, falls into the same category as bone.[1] In the accompanying figures I have epitomized the slow transformation of the single-fanged conical reptilian tooth, such as we see in the serpents, into the low-crowned human grinder. We now know all the transition forms, so that we can homologize each of the cusps of the human molar with its varied ancestral forms in the line of descent. For example, the anterior lingual or inner cusp of the upper true molars traces its pedigree back to the reptilian cone. The anterior triangle of cusps, or trigon, seen in the mesozoic mammalia, and persisting in the first inferior true molar of the modern dog, is still seen as the main portion of the crown of the human upper molars (*pr*, *pa*, *me*). To this was added, ages ago, the posterior lingual cusp, or hypocone, which, as Cope has shown, is exhibited in various degrees of development in different races and is an important race index.[1] A glance through the diagrams shows that the development of the crown has been by the successive addition of new cusps. Without entering upon the details of evidence, which would be out of place here, I may say briefly that the new main cusps have developed at the points of maximum wear (*i.e.*, use), and conversely in the degeneration of the crown, disuse foreshadows atrophy and disappearance.

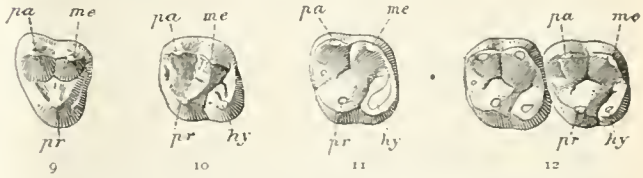


Key to Plan of Upper and Lower Molars in all Mammals.—Each tooth consists of a triangle, *trigon*, with the protocone, *pr*, at the apex. The apex is on the inner side of the upper molars and on the outer side of the lower molars.

Upon the whole, with some exceptions which we do not at present understand, the course of evolution of the teeth supports the evidence derived from the skeleton, that, whether any true causal relation has existed or not, the lines of individual transformation in the whole fossil series preceded those of race transformation.

The Rise of New Organs.—We owe to Dr. Arbuthnot Lane a most interesting series of studies upon the influences of various occupations upon the human body. He proves conclusively that individual adaptation not only produces profound modifications in the proportions of the various parts, but gives rise to entirely new structures.

His anatomy and physiology of a shoemaker[2] shows that the lifelong habits of this laborious trade produce a distinct type, which if examined by any zoölogical standard would be unhesitatingly pronounced a new species —*homo sartorius*. The psychological analysis which a Dickens or Balzac would draw, showing the influences of the struggle for existence upon the spirit of this little tailor could not be more pathetic than Dr. Lane's analysis of his body. The bent form, crossed legs, thumb and forefinger action, and peculiar jerk of the head while drawing the thread, are the main features of sartorial habit. The following are only a few of the results: The muscles tended to recede into tendons and the bony surfaces into which they were inserted tended to grow in the direction of the traction which the muscle exerted upon them. The articulation between the sternum and the clavicle was converted into a very complex arthrodial joint, constituting almost a ginglymoid articulation. The sixth pair of ribs were anchylosed to the bodies of the vertebræ, indicating that they had ceased to rise and fall with sternal breathing, and that respiration was almost exclusively diaphragmatic. The region of the head and first two vertebræ of the neck was still more striking: the transverse process of the right side of the atlas, toward which the head was bent, formed a new articulation with the under-surface of the jugular process of the occipital bone, "a small synovial cavity surrounded this acquired articulation, but there was no appearance of a capsular ligament;" the left half of the axis was united by bone to the corresponding portion of the third cervical; there was found a new upward prolongation of the odontoid



Evolution of the Human Upper Molars.—Fig. 9.—*Anaptomorphus*, a lower eocene monkey. Fig. 10.—An upper eocene monkey. Figs. 11 and 12.—Human, 11, Esquimaux; 12, negro. See addition of "talon," *hy*, to "trigon" composed of *pa*, *pr*, *me*.

[1] See especially the papers of Ryder, Cope, and the writer, "Evolution of Mammalian Molars to and from the Tritubercular Type," American Naturalist, 1889.

[1] The upper molars in many Esquimaux are triangular (as in Fig. 11); in most negroes they are square (Fig. 12). In our race they are intermediate.

[2] Journal of Anatomy and Physiology, 1888, p. 595.

peg of the axis, and a new accessory transverse ligament to keep it from pressing upon the cord. In short, "the anatomy of the shoemaker represents the fixation and subsequent exaggeration of the position and tendencies to change which were present in his body when he assumed the position for a short period of time.

Rate of Inheritance.—This illustration serves also to emphasize the great contrast between the rapidity of individual transformation and the slowness of race transformation. No one would expect the son of this shoemaker to exhibit any of these acquired malformations. Yet Dr. Lane thinks he has observed such effects in the third generation by the summation of similar influences.

All palæontological evidence goes to show that the effects of normal habits, if transmitted at all, would be entirely imperceptible in one generation. The horse, for example, has not yet completely lost the lateral toes which became useless at the end of the upper eocene period. This objection as to rate of evolution may be urged with equal force against the natural-selection theory. It is obvious that the active progressive principle in evolution, whatever it is, must contend with the enormous conservative power of inheritance, and this, to my mind, is one of the strongest arguments against the possibilities of the rise of adaptive organs by the selection of chance favorable variations in the germ-plasm.

Application to Human Evolution.—Principles underlying these illustrations may now be applied to some of the facts in human evolution brought out in the first lecture. They show that if functional tendencies are transmitted we can comprehend the distinct evolution history of each organ; the rise and fall of two organs side by side; the definite and purposive character of some anomalies; the increase of variability in the regions of most rapid evolution; the correlation of development, balance, and degeneration in the separate organs of the shoulder, hand, and foot.

Yet even granting this theory, there still remain difficulties. The relation of use and disuse to some of the contemporary changes in the human backbone is rather obscure. I would hesitate to pronounce an opinion as to whether our present habits of life are tending to shorten the lumbars, increase the spinal curvatures, and shift the pelvis, without making an exhaustive study of human motion. Among the influences which Dr. Lane has suggested[1] as operative here are the wearing of heeled shoes and the increase of the cranium. He considers the additional or 6th lumbar vertebra as a new element rather than as a reversion, and works out in some detail the mechanical effects of the presence of the fœtus upon female respiration (*i.e.*, in the sternal region) and upon the pelvis. Now, if it be true that the pelvis is larger in the higher races than in the lower, I do not think that Dr. Lane can sustain his point, because in the lower races the fœtus is carried for an equally long period, during a much more active life, and in a more continuously erect position. Therefore, if these mechanical principles were operating, the pelvis in the modern lower races should be larger than in the higher. On the other hand, the form of the female pelvis in the higher races is one of the best established selecting or eliminating factors, a large pelvis favoring frequent births and the preservation of those family stirps in which it occurs. I mention this to show how cautious we must be in jumping to conclusions as to kinetogenesis.

The transformism in all the external features of the skull, jaws, and teeth may be attributed to inherited tendencies toward hypertrophy or atrophy; but how about the convolutions of the turbinal bones or the complex development of the semicircular canals and cochlea of the internal ear and the many centres of evolution which are beyond the influences of use and disuse? These are examples of structures which fortify Weismann's contention, for if complex organs of this character can only be accounted for by natural selection, why consider selection inadequate to account for all the changes in the body?

Difficulties in the Natural-Selection Theory.—The answer, I think, is readily given: We do not know whether use and disuse are operating upon the mechanical construction of the ear; we do know that the organ can be rendered far more acute by exercise; but even if it were true that habit can exert no formative influence, the ear is one of those structures which since its first origin has been an important factor in survival, and may therefore have been evolved by natural selection. Now the very fact that selection may have to care for variations in such prime factors in survival as the ear, renders it the more difficult to conceive that it also is nursing the minutiæ of variation in remote, obscure, and uncorrelated organs.

Even in the brief review of human evolution in the first lecture I have pointed out eight independent regions of evolution, upward of twenty developing organs, upward of thirty degenerating organs. A more exhaustive analysis would increase this list tenfold. Now, where chance variation should produce an increase in size in all the developing organs, and a decrease in size of all the degenerating organs, and an average size in all the static organs, we would have all the conditions favoring survival. But the chances are infinity to one against such a combination occurring unless the tendencies of variation are regulated and determined, as Lamarckians suppose, by the inheritance of individual tendencies. But may not the favorable variations in the body be grouped to either outweigh or underweigh the unfavorable variations? This would be possible if combinations occurred, but we can readily see that combinations, such as we observe in the separate elements in the foot alone, completely neutralize each other so far as "survival" is concerned; how the foot would neutralize the hand, or the foot and hand would neutralize the lumbar region.[1]

It is this consideration of single organs, the observation of their independent history, the rise of new compound organs, by steady growth from infinitesimal beginnings of their separate elements, the combined testimony of anatomy and palæontology which force us to regard the theory of evolution by the natural selection of chance variations as wholly untenable. With the utmost desire to regard the discussion in as fair a spirit as possible, the explanations offered by the adherents of Weismann's doctrine strike me as strained, evasive, and illogical.[2]

We can, however, by no means undervalue or dispense with natural selection, which must be in continuous operation upon every character of sufficient importance to weigh in the scale of survival. I need hardly remind you that this selecting principle was first discovered in 1813 by Dr. W. C. Wells, of Charleston, in connection with the immunity from certain tropical diseases enjoyed by negroes and mulattoes.[3]

The eliminating factor in selection is illustrated almost daily in cases of appendicitis. I regret I have not had time to ascertain whether or not this disease is considered due purely to accident or to congenital variation in the aperture of the appendix, which favors the admission of hard objects. If so, modern surgery is only benefiting the individual to the detriment of the race by its efficient preventive operations; and every individual who succumbs to this disease can reflect with melancholy satisfaction that he does so *pro bono publico*.

Conclusions as to the Factors of Evolution.—The conclusions we reach from the study of the muscular and skeletal systems are therefore as follows: 1st. That individual transformism in the body is the main determinant of variations in the germ cells, and is therefore the main cause of definite progressive or retrogressive variations in single organs. 2d. That evolution in these organs is

[1] Journal of Anatomy and Physiology, 1888, p. 219.

[1] I have expanded this idea fully in recent papers upon the theory of evolution of the horse. See "Are Acquired Variations Inherited?" American Naturalist, February, 1891.

[2] See Weismann's last essay, Retrogressive Development in Nature, Biol. Mem., trans., in press.

[3] See Introduction of Darwin's Origin of Species.

hastened, where all members of the race are subject to the same individual transformism. The contrast between the rate of individual transformism and race transformism is due to the strong conservative forces of the germ-plasma. 3d. That evolution is most rapid where variations are of sufficient rank to become factors in survival. Then selection and use-inheritance unite forces, as active progressive principles opposing the conservative principle in the germ-plasma. 4th. That fortuitous and chance variations also arise from disturbances in the body or germ-cells; they may be perpetuated, or disappear in succeeding generations.

Applying these views to variation there should, theoretically, appear to be just those two distinct classes of anomalies in the human body which we have seen actually occurring. First, those in the path of evolution, arising from perfectly normal changes in the somatoplasm and germ-plasm. Second, those wholly unconnected with the course of evolution, arising fortuitously or from abnormal changes in the somatoplasm or germ-plasm; to this head may be attributed the whole scale of deformities. Thus transformism and de-formism should be kept distinct in our minds. Nevertheless the facts of de-formism contribute the strongest body of evidence which we can muster at present to prove that there does exist a relation between the somatoplasm and germ-plasm which renders transformism possible.

The Relations between the Somatoplasm and Germ-plasm.—We have seen reasons to take a middle ground as to the distinct specific nature of the body cells and germ cells, and this position is, I think, strengthened the more broadly we extend our inquiry into all the fields of protoplasmic activity.

There are three questions before us.

1. What is the evidence that the germ-plasm and somatoplasm are distinct?

2. What is the specific nature of the germ-plasm?

3. What is the nature of the relations which exist between the two?

1. The *separation of the germ-plasm* is in the regular order of evolution upon the principles of physiological division of labor. The unicellular organisms combine all the functions of life in a single mass of protoplasm, that is, in one cell. In the rise of the multicellular organisms the various functions are distributed into groups of cells, which specialize in the perfecting of a single function. Thus the reproductive cells fall into the natural order of histogenesis, and the theory of their entire separation is more consistent with the laws governing the other tissues than the theory which we find ourselves obliged to adopt, that while separate they are still united by some unknown threads with the other cells.

The morphological separation of what we may call the race-protoplasm becomes more and more sharply defined in the ascending scale of organisms. Weismann's contention as to the absolutely distinct specific nature of the germ-plasm and somatoplasm has, however, to meet the apparently insuperable difficulty that in many multicellular organisms, even of a high order, the potential capacity of repeating complex hereditary characters, and even of producing perfect germ-cells, is widely distributed through the tissues.

For example, cuttings from the leaves of the well-known hot-house plant, the begonia, or portions of the stems of the common willow-tree, are capable of reproducing complete new individuals. This would indicate either that portions of the germ-plasm are distributed through the tissues of these organisms, or that each body-cell has retained its potential quota of hereditary characters.

Among the lower animals we find the same power; if we cut a hydra or bell-animalcule into a dozen pieces, each may reproduce a perfect new individual. As we ascend in the animal scale the power is confined to the reproduction of a lost part in the process known as recrescence. As you well know, in the group to which the frog and salamander belong, a limb or tail, or even a lower jaw, may be reproduced. The only logical interpretation of these phenomena is, that the hereditary powers are distributed in the entire protoplasm of the organism, and the capacity of reproduction is not exhausted in the original formation of the limb, but is capable of being repeated. There has been considerable discussion of late as to the seat of this power of *recrescence*. It seems to me not impossible that, in the vertebrates it may be stored in the germ-cells, and it would be very interesting to ascertain experimentally whether removal of these cells would in any way limit, or affect this power; we know that such removal in castration or ovariotomy sometimes profoundly modifies the entire nature of the organism, causing male characters to appear in the female, and female characters to develop in the male.

So far as man is concerned it has been claimed by surgeons that genuine recrescence sometimes occurs; for example, that a new head is formed upon the femur after exsection; but my friend Dr. V. P. Gibney informs me that this is an exaggeration, that there is no tendency to reproduce a true head, but that a pseudo-head is formed, which may be explained upon the principle of regeneration and individual transformism by use of the limb.

Pflüger's opinion is that recrescence does not indicate a storage of hereditary power, that there is no pre-existing germ of the member, but that the re-growth is due to the organizing and distributing power of the cells at the exposed surface, so that, as new formative matter arrives, it is built up gradually into the limb. This view would reduce recrescence to the level of the *regeneration* process which unites two cut sections of the elements of a limb in their former order. It is partly opposed to the facts above referred to, which seem to prove the distribution of the hereditary power. Yet it seems to me quite consistent to consider these three processes—*a*, reproduction of a new individual from every part; *b*, recrescence of a new member from any part; *c*, regeneration of lost tissues—as three steps indicating the gradual, but not entire withdrawal of the reproductive power into the germ-cells.

I have not space to consider all the grounds which support the view of the separation of the germ-cells in man. Some of the more prominent are: the very early differentiation of these cells in the embryo, observed with a few exceptions in all the lower orders of animals, and advancing so rapidly in the human female that several months before birth the number of primordial ova is estimated at seventy thousand, and is not believed to be increased after the age of two and a half years. The most patent practical proof is that we may remove every portion of the body which is not essential to life and yet the power of complete reproduction of a new individual from the germ-cells is unimpaired. Among the many reasons advanced for pensioning the crippled soldiers of our late war you never hear it urged that their children are incapacitated by inheritance of injuries. The strongest proof, however, rests in the evidence I have already cited from heredity of the extraordinary stability of the germ-cells, which is the safeguard of the race.

2. The *specific nature of the germ-plasm* must be considered before we consider its relations. Wherein lies the conservative power of the germ-plasm, and in what direction shall we look for its transforming forces? You see at once that marvellous as is the growth of cells in other tissues, the growth of the germ-cell is still more so.

We find it utterly impossible to form any conception of the contents of the microcosmic nucleus of the human fertilized ovum, which is less than $\frac{1}{250}$ of an inch in diameter, but which is, nevertheless, capable of producing hundreds of thousands of cells like itself, as well as all the unlike cells of the adult organism. We can only translate our ideas as to the possible contents of this nucleus in the terms of chemistry and physics.[1]

[1] See Ray Lankester, Nature, July 15, 1876.

Spencer[1] assumed an order of molecules or units of protoplasm lower in degree than the visible cell-units, to the internal or polar forces of which, and their modification by external agencies and interaction, he ascribes the ultimate responsibility in reproduction, heredity, and adaptation. This idea of biological units seems to me an essential part of any theory; it is embodied in Darwin's "gemmules," in Haeckel's "plastidules," yet, as Lankester says, the rapid accumulation of bulk is a theoretical difficulty in the material conception of units. In the direction of establishing some analogy between the repetition power of heredity and known function of protoplasm, Haeckel[2] and Hering[3] have likened heredity to memory, and advanced the hypothesis of persistence of certain undulatory movements; the undulations being susceptible of change and therefore of producing variability, while their tendency to persist in their established harmony is the basis of heredity. Berthold, Gautier, and Geddes[4] have speculated in the elaboration of the idea of metabolism; the former holding the view that "inheritance is possible only upon the basis of the fundamental fact that in the chemical processes of the organism the same substances and mixtures of substances are reproduced in quantity and quality with regular periodicity."[5]

I have merely touched upon these speculations to show that the unknown factors in heredity are also the unknown factors in operation in living matter. All we can study is the external form, and conjecture that this form represents matter arranged in a certain way by forces peculiar to the organism. These forces are exhibited or patent in the somatic cells; they are potential or latent in the germ-cells.

The last stage of our inquiry is as to the mode in which the action of habit or environment upon the somatic cells can be brought to bear upon the germ-cells.

The Nature of the Relation Between the Body-cells and Germ-cells.—I have already shown that we are forced to infer that such a relation exists by the facts of evolution, although these facts show that the transmission of normal tendencies from the body to the germ-cells is ordinarily an extremely slow process.

Virchow[6] says every variation in race character is to be traced back to the pathological condition of the originator. All that is pathological is not diseased, and inheritance of a variation is not from the influence upon one individual necessarily, but upon a row of individuals. This is in the normal condition of things. In the abnormal condition the rate of transmission may be accelerated.

Does this transmission depend upon an interchange of material particles, or upon an interchange of forces, or both?

There are three phenomena about which there is much scepticism, to say the least, which bear upon the question of a possible interchange of forces between the body and the germ-cells. These are the inheritance of mutilations, the influence of previous fertilization, and the influence of maternal impressions. They are all in the quasi-scientific realm, which embraces such mental phenomena as telepathy. That is, we incline to deny them simply because we cannot explain them.

Mutilations.—Since the publication of Weismann's essays the subject of inherited mutilations has attracted renewed interest. I would first call attention to the fact that this matter has only an indirect bearing, for a mutilation is something impressed upon the organism from without; it is not truly "acquired;" the loss of a part by accident produces a sudden but a less profound internal modification of the organism than the loss of a part by degeneration. Most of the results are negative; many of the so-called "certain" cases prove upon investigation to be mere coincidences. Weismann[1] himself experimented upon white mice, and showed that nine hundred and one young were produced by five generations of artifically mutilated parents, and yet there was not a single example of a rudimentary tail or of any other abnormality in this organ. The cases of cleft ear lobule have recently been summed up.[2] Israel reports two cases of clefts in which the parent's ears were normal. Schmidt and Ornstein report affirmative cases. His shows that an affirmative case, cited by V. Zwieciki, is merely an inherited peculiarity. The entire evidence is unsatisfactory, and, upon the whole, is decidedly negative.

Not so, however, in cases where the mutilation results in a general disturbance of the normal functions of different organs, as in the experiments conducted by Brown-Séquard[3] upon guinea-pigs, in which we see "acquired variation" intensified. In these, abnormal degeneration of the toes, muscular atrophy of the thigh, epilepsy, exophthalmia, etc., appeared in the descendants of animals in which the spinal cord or sciatic nerve had been severed, or portions of the brain removed. It was also shown that the female is more apt to transmit morbid states than the male; that the inheritance of these injuries may pass over one generation and reappear in the second; that the transmission by heredity of these pathological results may continue for five or six generations, when the normal structure of the organs reappears. These cases, which are incontestable, at first sight appear to establish firmly the transmission of acquired characters; they were so regarded by Brown-Séquard. These lesions act directly upon the organs, and the abnormal growth in these organs appears to be transmitted. But can they not be interpreted in another way, namely, that the pathological condition of the nerve-centres has induced a direct disturbance in those portions of the germ cells which represent and will develop into the corresponding organs of the future offspring?

Previous Fertilization.—Consider next the influence exerted upon the female germ-cell by the mere proximity of the male germ-cell, as exhibited in the transmission of the characteristics of one sire to the offspring of a succeeding sire, observed in animals, including the human species, also in plants. The best example is the oft-quoted case of Lord Morton's mare, which reproduced in the foal of a pure Arab sire the zebra markings of a previous quagga sire.

Some physiologists[4] have attempted to account for these remarkable indirect results from the previous fertilization or impregnation, by the imagination of the mother having been strongly affected, or from interchange between the freely inter-communicating circulation of the embryo and mother, but the analogy from the action in plants (in which there is no gestation but early detachment and development of the fertilized cells) strongly supports the belief that the proximity of male germ-cells acts directly upon the female cells in the ovary. All that we can deduce from these facts is that in some manner the normal characteristics and tendencies of the ova are modified by the foreign male germ-cells without either contact or fertilization.

Maternal Impression.—The influence of maternal impressions in the causation of definite anomalies in the fœtus is largely a matter of individual opinion.

It is denied by some high authorities, led by Bergman and Leuckhart.[5] Most practitioners, however, believe

in it, and I need hardly add that it is a universal, popular belief,[1] supported by numerous cases. I myself am a firm believer in it. The bearing which the subject has upon this discussion is this: if a deviation in the development of a child is produced by maternal impression, we have a proof that a deviation from normal hereditary tendencies can be produced without either direct vascular or nervous continuity.

We see an analogy between the experiments of Brown-Séquard, the influence of the previous sire, and the maternal influence. Neither, in my opinion, directly supports the theory of transmission of acquired characters, for they do not prove that normal changes in the body-cells directly react upon the germ-cells; they all show that the *typical hereditary development of single organs may be diverted by living forces which have no direct connection* with them according to our present knowledge.

What the nature of these forces is, I will not undertake to say; but I believe we must admit the existence of some unknown force, or rather of some unknown relations between the body-cells and germ-cells.

A year ago, recognizing fully the difficulty of advancing any theory of heredity which would explain the transmission of acquired characters, I came to the following result: "It follows as an unprejudiced conclusion from our present evidence that upon Weismann's principle we can explain inheritance but not evolution, while with Lamarck's principle and Darwin's selection principle we can explain evolution, but not, at present, inheritance. Disprove Lamarck's principle and we must assume that there is some third factor in evolution of which we are now ignorant."

In this connection it is interesting to quote again from my colleague, Professor E. B. Wilson. He writes that the tendency in Germany at present is to turn from speculation to empiricism, and this is due partly "to the feeling that the recent wonderful advances in our knowledge of cell phenomena have enormously increased the difficulties of a purely mechanico-physical explanation of vital phenomena. In fact, it seems that the tendency is to turn back in the direction of the vital-force conception. . . . As Boveri said to me recently. 'Es gibt zu viel vorstand in der Natur um eine rein mechanische Erklärung der Sache zu ermöglichen.'"

In the final lecture we turn to the forces exhibited in the germ-cells.

(To be continued.)

Hot Bathing in Japan.—In hygienic matters the Japanese have everywhere a habit which may have a lesson for us. In their nightly bath and morning wash the water is never cold, never warm, but always as hot as it can be borne. To foreigners this habit seems very surprising, but the most inveterate Englishman, if he stays in the country long enough, abandons his cold tub in its favor. The cold-taking which it is suspected must follow it is found not to occur if the water has been hot enough. This heat is maintained by a little furnace beneath the bath. In the bath the bather or bathers take a prolonged soaking, the washing proper being done on the bath-room floor; then follows a second and final soaking, drying with towel, and a lounge in bathing wrapper. This habit seems to promote softness and suppleness of the skin, and by persons inclined to rheumatism is soon found to be altogether preferable to the cold bath in every particular. The poorest of the Japanese hear of a cold bath with amazement, and would be sure the man who used it must be a barbarian. With respect to the superiority of the hot bath over the cold, I have come to find that in my own case certainly the Japanese are right.—Dr. Benjamin Howard, in the *Lancet*, January 16, 1892.

"Have Your Teeth Pulled Out for a Christmas Present," was the cheerful sign displayed by a London dentist for a few weeks before the holidays.

THE SINGER'S THORAX.

By W. T. ENGLISH, M.D.,

PROFESSOR OF PHYSICAL DIAGNOSIS, WESTERN PENNSYLVANIA MEDICAL COLLEGE, AND LECTURER ON VOCAL HYGIENE AT DUQUESNE COLLEGE, PITTSBURG, PA.

The lungs and heart of the habitual singer are engaged in mutual digressions from stability in behavior. Therefore we must consider these organs conjointly. The heart normally performs four complete cycles during one respiratory act. This order constitutes the rhythm. But the vocalist extends the expiratory effort over the time occupied by forty or fifty heart-throbs, and almost effaces the respiratory pause and inspiratory period. Besides this disturbance of the elements constituting the act a unit, there is a breach in the equilibrium normally existing between the heart and the lungs. Admitting that there is reciprocity in these acts and their elements which permits, for a season, more or less variation, there must be evil follow the deviations from natural rhythms, but with so small influence as to escape analysis. There is an unanimity of purpose in the close relation of these two vital organs, and it is for the dual functionation, denominated elimination and oxygenation. In these functions the heart is too often left out of the account, whereas the lungs should be regarded as the more passive agents, and the heart the active factor, in both functions. It will be admitted that these functions must be trammelled if the heart is sending through the lungs the entire contents of the circulation during one prolonged expiratory effort. It is a fact that during the execution of forty to fifty heart-cycles the entire amount of blood in the body is pumped through the organ. The demands for oxygen and elimination are among the main promoters of rhythmic behavior of the heart and lungs, and therefore an added difficulty is forced in the way of their concerted action every time the musical executant utters a prolonged phrase. There will speedily follow a disturbance manifested by irregular contractions of the heart. The pulse may exhibit tachycardia or bradycardia, due to the vacillating nervous and muscular tonicity of the cardiac muscle. The nerve elements which animate the heart and preserve it in equipoise—the ganglia—are first confused, then become aberrate, and finally insane. In the complex of the acts of the singer's heart, we observe the consequences of habitual interference with normal movements, resulting from exercise of the will, and sooner or later, as a concomitant, appears a physiological disturbance of function, which augments the difficulties in geometric ratio. Thus is forced upon the heart, insidiously but surely, a permanent unstable equilibrium. As one of the direct and natural results of the want of equilibrium, we find that the vocalist is forced into the extremes of pulmonary activity by slight causes. In other words, the singer is easily "winded," in consequence of exercise outside of his customary vocation. The circumstances and physiological factors contributing to establish and maintain this peculiar form of dyspnœa, become more simple and obvious as the investigation proceeds. The gradations may be found to prevail from eupnœa to the profoundest dyspnœa or opnœa. The initiatory is usually a sighing or a simple desire for longer inspiration, apparent in the quiescent state of the subject. "Shortness of breath" is the common expression which conveys the experience of the patient to his physician. The actor who mingles gesture with singing and varying posture, finds that positions he once assumed are accomplished with greater difficulties to the respiratory acts than formerly. The phrases which once were executed with comparative ease become difficult, if not impossible, and, to give them needed force. it is necessary to divide them. These conditions are rarely observed until the subject is well along in the thirties, although I have met with a number who became

conscious of the oppression as early as twenty-five. Among those earliest influenced the women predominate. Contrary to a reasonable anticipation, I noticed that those who exhibited the greatest lung area and presented the barrel-shaped chest, gave the most typical form of the singer's dyspnœa. It is readily demonstrated that increased mobility of the lungs and thorax do not follow enlargement of the pulmonary apparatus. As long as the singer continues to exercise the lungs they increase in dimensions; but this augmentation in size is due to an increase in the circulatory area of the pulmonary apparatus. The forcible expiratory efforts irregularly effected, the constant practice, the persistent exercise during day and night by the professional vocalist, continued for months, and even years, uninterruptedly, form a procession of influences, the contemplation of which must evolve rational thoughts of the abnormal character of strength thus achieved. The heart feels the demand for increased systolic power, especially in the thin right ventricle, which is subjected to the major portion of the stress, and nature responds with hypertrophy. The first demand for hypertrophy supplies the need not only, but tends to further enlarge the area of the pulmonary circulation. The pulmonary capillaries will continue to dilate and augment in size and number. The increased blood-pressure is noticed mainly in the capillaries surrounding the vesiculi. By the amplification of the capillary vessels they exert pressure upon the alveoli, indenting their walls and limiting the breathing membrane. Although this area be amplified, the pulmonary artery inlet and the outlet of the pulmonary veins continue of their former calibre. Thus related, the openings present to the abnormally widened pulmonary circulation the condition of relative narrowing. These circumstances impart to the pulmonary capillary system the character of erectile agents, and they confer upon the lungs thus exercised their rotundity and apparent development without corresponding elasticity. On the other hand, the conditions described are unfavorable to the interchange of gases, and the blood may acquire a dyspnœic character. The greater the excursions of the alveolus, the better the blood is aërated; but their mobility is decreased by the rigidity thus attained. To these barriers to a free respiration may also be added the influence upon the heart of the encroachment upon the area of the thorax by the enlarged volume of lungs, and its abnormal persistence. This increased fulness of the chest can only proceed without decisive embarrassment of the respiratory acts to the limit where the environments begin to act as obstructions. To recapitulate: As long as the singer continues to exercise the lungs, the larger they grow. The heart, which is the only organ that is unceasing in its relative increase until age, also takes on an undue augmentation in bulk. The environments assume a greater rigidity, and cease to develop at a time when ossification approaches completion, as would be in the thirties. Thus, I think, are explained the phenomena of the singer's dyspnœa in a rational and physiological manner

One long familiar with the study of the singer's thoracic organs will scarcely fail to observe a peculiar disposition to neurotic irritability of the heart. To become a singer or dramatic reader requires that there be an inherent sensitive or irritable nervous system. In some cases the nervous system itself may be well preserved, and yet the neurosal element do mischief by spurring on the already goaded heart and lungs. The constant assumption of passions always severer than the genuine, the attempts to appear at ease when most uncomfortable, the prolonged mental excitement lasting for all the hours of a performance—not limited to the time of the presence of the artist before the audience—all bespeak an abnormal altitude in the neurosal irritation, which might excuse the hysterical experiences so common among those of the operatic and concert stage. The pose of a dramatic singer or reader is rarely natural and easy. Unnatural rigidity of the muscles prevails. Coldness of the extremities intimates the interference with the peripheral circulation; lividity of the lips and tremor cordis betray the exalted neurotic pressure. Directly and indirectly appear the results of this overwrought nervous influence through the medium of cardiac misbehavior. In all foudroyant effects, which are so sudden and overwhelming in some of the graver forms of heart maladies, there appear the obvious evidences of momentary nervous shock and emotion. The absence of such considerations, in our estimate of heart demeanor, makes all investigations vague, changeable, and misleading.

For years the hypertrophy is regulated so neatly to the demand for compensation in the heart-muscle, and the persistence and severity of the vocal excesses, that the changes going on are fairly masked to all but the most careful diagnostician. This may continue until an interruption of the vocal activities, or a complete cessation of the accustomed exercise. Then they may be called from obscurity in a sudden and alarming manner in consequence of a diminution in the hypertrophy without a corresponding subsidence of the pulmonary requirements. Injuries which force the singer into the quiescent state, and compel the recumbent position, furnish the purest examples of cardiac debility succeeding upon abstinence from vocal exertion. I find in my notes several of these cases. A striking one is that of a man, aged thirty-three, and a constant singer, who had broken his thigh, was anæsthetized with chloroform while the fracture was dressed. He remained recumbent nearly six weeks with but occasional changes of position. In his earliest attempts to move upon crutches he suddenly became faint and fell to the floor, reproducing the fracture. He was then sent to the hospital to afford more perfect surveillance; chloroform was again exhibited preparatory to redressing the fracture; but after a few inefficient inhalations his heart ceased to beat forever. The autopsy revealed no abnormalities sufficient to contribute to death, except large lungs and engorged and dilated right heart. I think this case will suffice to illustrate the theory I assume. It has been obvious enough to my mind, for some years, that a condition does uprise in the singer's heart when abstinence from wonted activity will permit muscular deterioration and dilatation. At all times and in all cases, there is an unstable equilibrium produced by the varying character of the efforts—ranging from active hypertrophy to dilatation, and back again—and these in perfect accord with the varying degrees of exercise and rest. Thus is proven one fact that I desire to urge, viz.: That the true cardiac gymnastics for the vocalist are the more or less protracted exercises to which he has accustomed himself, and in the absence of such stimulus to his heart muscle, the necessity of the oversight of his physician. Especially should these observations be noted in cases where the symptoms of dilatation have already shown themselves. Hearts once impaired, depleted, and impoverished, need but slight insult to permit the occurrence of an incurable lesion.

The fatal disposition of diseases invading the chest of the active vocalist has failed of its merited significance, and scanty data are furnished, rather from want of opportunity or time for observation than absence of facts corroborative of the assumption. In self-limiting maladies the integrity of the heart-muscle is the one important anchorage of our hopes. Acute heart maladies add to the sum of their dangers when they invade a heart long irritated by overwork. Owing to the unstable character of the right side, the left side lesion, in these cases, has but a short course to run, and that without expenditure of much time, in producing the secondary sequelæ. Pneumonitis claims as fatal fifty per cent. of the vocalists attacked. Many of our world renowned singers have succumbed to acute inflammation of the lungs. In my experience, an average pneumonitis or endocarditis is, for the vocalist as to none other, a sure passport to the beyond. Such diseases of the membranous portions of the

breathing apparatus as the varied forms of bronchitis, pleuritis, etc., are unusually difficult of management, and are more acute and dangerous to life. Diphtheritic poison has a specific affinity for the tissues in which the well-being of the vocalist is directly concerned. Diphtheritic croup becomes a probability to boys affected with diphtheria, and who keep their immature vocal organs under stress in boy choirs. Besides the character of severity, may be added the proneness to these maladies incident to the high blood-pressure constantly maintained in the lungs and air passages. With this mutual digression from stability of demeanor in the thoracic organs, there are necessarily involved other functions and organs not within the province of this paper to discuss. Vascular diseases may follow as a sequence to the backward obstruction into the veins, and the influence of bodily decline upon the cardiac muscle of the singer is very obvious and deplorable.

The diagnosis as to the condition of the lungs can readily be made out. There is on inspection a large barrel-shaped chest in most cases. There is an evident want of correspondence between the size of the chest and inspiration and expiration. Unless these acts are urged, they are not marked by force as would be expected from the chest development. Palpation often reveals the intercostal spaces wide, and the thoracic movements superficial and accelerated. Percussion discovers a lowered percussion note due to tension of walls and large and compact lungs. Auscultation reveals the vesicular murmur intensified, with a tendency to puerile respiration. Jerky respiration is sometimes observed over various portions of the lungs.

As to the heart, inspection, palpation, and percussion are all deprived of their customary exactness on account of the extension of the chest walls, which are usually muscular, as well as the augmentation in the bulk of the lungs, which forces over the triangular space, commonly exposing the heart, a heavy cushion of lung-tissue. Under most favorable circumstances the right side of the heart is obscure, and enlargements are often matters of inference. Auscultation is our best method of physical diagnosis, and the exquisite click of the pulmonary semilunar valves, with the decisive accentuation of the second sound, are corroborative of other evidences adduced from the vocation, history, and age of the patient. The accentuated pulmonary valve-sound intimates tension of the pulmonary circulation only, but if it has so continued its efforts for months, we infer there is hypertrophy of the right ventricle. Therefore we mainly depend upon the accentuation of the pulmonary valvular sound together with the history, as before mentioned, to establish hypertrophy. Dilatation is so sudden and unpremeditated, and its results so startling, that the history is mainly to be relied upon. The vacillating character of the heart-muscle makes one investigation contradictory to the other, and the want of stability of the heart-muscle is thereby established.

As to prognosis: The age at which the vocalist begins his efforts has much to do with his future. The heart has its special periods of rapid development, and alternates with others of quieter increase. During that important transition period existing between puberty and maturity, the heart is found to double its bulk. So that at twenty-one years the heart is just twice as large as at sixteen. It is harmful at this time to encumber the action of the heart by extremes of vocal exercise. Assiduity and ambition favor excesses, and contribute to the dangers in the path of the student of vocal music at any age. The halo of glory which hangs about the head of the precocious vocalist, comet-like, threatens while it shines. Those who gradually accustom themselves to the exercise will longest postpone the zenith of difficulties, and they who with similar gradations subside from its activities will best withstand. Nevertheless, a permanent abnormal energy of the heart, a pulmonary rigidity, and a barrel-shaped chest are acquisitions of the chronic vocalist. Signs of cardiac debility should deter any one from vocal study. To attempt proficiency in the presence of functional derangements would be ill advised, and if positive lesions exist vocal exercises would be foolhardy.

Sex considerations prove that in ordinary heart maladies women are more often exempted, partly because of their absence from the exciting causes common among men, and also because of their less laborious vocations and freedom from exposure. In these forms of heart difficulty, in each particular, these rules are reversed. Women are more often students of vocal music, are more persistent and painstaking, and more frequently aspire to the stage than men. They are, as a class, more severely tried by vocal efforts because of peculiar respiration, neurosal tendencies, special functions, and manner of dress. The results come earlier in life to women, and may be estimated as belonging to an age at least one quinquenaud below that of men.

In making up a prognosis it would be well to keep in mind the fact that right-sided hypertrophy, even if perfectly compensating, is more evanescent, and for many, and for the most part obvious, reasons, cannot be regarded as beneficent or as reliable as left-side hypertrophy. Complete compensation may in these cases be preserved for years, and even though enforced rest from injury or prolonged illness reduce the heart capacity, a knowledge of the causes and conditions as here presented will enable a rational and effective resort to therapeutics, on the part of the physician, which will redound to the patient's physical welfare.

AN ENORMOUS CONGENITAL UMBILICAL HERNIA WITHOUT CUTANEOUS COVERING—OPERATION—RECOVERY.

By SAMUEL C. BENEDICT, M.D.,

VICE-PRESIDENT NATIONAL ASSOCIATION RAILWAY SURGEONS, ATHENS, GA.

At 6 A.M. Saturday, January 9, 1892, I delivered, instrumentally, Mrs. C. D. F——, primipara, aged thirty-three, of a large male child, approximating ten pounds in weight, well-formed and rounded, and of perfect development, with the exception of the anterior walls of the abdomen around the umbilical cord, as described below. Presentation, R. O. A.

Upon raising the bedclothes to tie the cord, I found a protrusion of the abdominal viscera through a circular opening in the abdominal wall four inches in diameter, the tension upon the cord materially increasing the protrusion. Quickly tying the cord and dividing it, I handed the child to the nurse, with directions to say nothing, but to keep her hand firmly pressed down upon the protruding mass. After having given the mother the necessary attention, I had the child moved to the adjoining room for dressing, and there, upon further examination, found the following condition:

There was an entire arrest of development in the skin and muscles of the umbilical region of the abdomen, the edges of the skin forming a perfect circumference of a circle whose radii were two inches, and adherent by a rounded edge to the peritoneum and reflected covering of the cord, which was spread over the whole mass adherent to the mural peritoneum. The umbilical cord passed out from the lower edge of the hernia, and one and a half inch from the pubis. The color of the mass at birth was a dark bluish-black, and the coverings so thin that the movements of the viscera within could be seen. Realizing that I had a desperate condition of affairs to deal with, and being undecided just then what to do, I covered the whole mass with dry bichloride gauze, bandaged firmly with a flannel roller an inch and a half wide, and had the child dressed, giving directions to handle carefully and prevent crying as much as possible. The same day I began to hunt up authorities upon umbilical hernia, and failed absolutely to find in any work on surgery at my command any report upon or instructions for dealing with such a case. Wyeth, Ashhurst, Erichsen, Reference Handbook, etc., were searched, but in vain.

In Gross's "Surgery," vol. ii., p. 712, issue of 1859, is a very accurate description of the condition, and the only thing of the kind I could find. He says: "When umbilical hernia is large, death usually takes place in a few days after birth from the effects, apparently, of peritoneal irritation. If the child survive, an attempt may be made," etc. Seeing no possible chance for this child to survive with the large area of peritoneum to be exposed when the cord covering should slough off, I decided that there was nothing to do but to attempt an operation. Accordingly, on Monday, January 11, 1892, and fifty-three hours after birth, the operation was made. With the assistance of Dr. James C. Bloomfield and Dr. John Gerdine, the latter giving the anæsthetic, I began by attempting to dissect up the now dead and yellowish-white membrane covering the peritoneum. This was the most difficult part of the whole work, as it was firmly adherent to the external surface of the mural peritoneum, and the dissection had to be carefully done in order to avoid tearing or cutting the peritoneum, which was as thin as a cobweb and tore upon the slightest tension, exposing more than once the cavity. After dissecting off, as best I could, to the skin circumference, I divided, close down to the lower portion of the wound, the umbilical cord and vessels, now a dried and shrivelled mass and giving no blood upon section. It had been hoped that I could pare the rounded edges of the skin and, by tension upon it, invaginate the peritoneum and so approximate the edges in a perpendicular line. This was found impossible, as, besides the firm union of the skin to the peritoneum, the liver and spleen occupied a large portion of the hernia, the intestines being at the lower portion only. I then penetrated the skin circumference with a pair of fine-pointed conjunctival scissors, curved on the flat, and cut the skin closely to the peritoneum all the way around, leaving a ring of skin an eighth of an inch wide, approximately, still adherent to the peritoneum. The skin was then dissected up for two or three inches to the sides before sufficient was obtained to approximate, and even then with difficulty, by reason of the great intra-abdominal pressure.

The approximation was made upon the subcutaneous surface rather than upon edge of skin, in order to get a broader contact. This was held together by three silver pins, an inch long, wound with silk in the figure of 8 way, and intermediate apposition obtained by black silk interrupted sutures. The line of approximation was about four inches long, and perpendicular, and this was first dusted with iodoform, strengthened by adhesive plaster, covered by narrow strips of rubber tissue, bichloride gauze, cotton, and a firm flannel bandage. Bichloride solution was used for personal cleanliness, carbolic acid for instruments, and boiled sodium chloride solution for wound surfaces.

The operation lasted fifty minutes, the child, two days' old, taking only half an ounce of chloroform and rallying promptly and in good condition. Directions were given for one drop of paregoric every hour or two, if necessary to quiet the child, and we left, satisfied that peritonitis would develop within forty-eight hours. We were agreeably disappointed. There was never any elevation of temperature or abnormal rapidity of heart's action, the child resting nicely with not over an average of a drop of paregoric every four hours.

The wound was not examined until the third day, when it was found that the skin had become adherent over the peritoneal surface and along the line of approximation, although there was considerable redness a half inch or more outside of this line, this gradually subsiding. Upon the fifth day it was found that the tension had loosened the silver pins, so that they, with the sutures, were removed and their place supplied by adhesive strips. On the tenth day I found a separation of the edges about an inch in length, and exposing a granular space of peritoneum one-quarter of an inch wide at the widest part. This was drawn together by strapping, and a rubber plaster band, three inches wide, passed around the body, and laced over the gauze covering the wound, answering the purpose of resisting the great intra-abdominal pressure so well that to-day, January 30th, there is complete union everywhere. The child has never acted other than any child of its age, has nursed regularly and with avidity, bowels and bladder acting normally. Paregoric has been used occasionally, chiefly at night, but never over six drops during the entire night, and the child was always easily aroused from sleep. There is now nothing to show for the hernia but the line of cicatrization, four inches long, which is a finer truss than anything else could be.

When the little fellow cries or strains there is a slight round bulging at the umbilical opening, but not enough to give cause for further uneasiness, and this is kept down by a silk elastic bandage, four inches wide and thirteen inches long, made by Williams & Co., of Baltimore. The child, of course, has no navel, and never will, and if he lives long enough may some day be, upon the Tom Sawyer principle, the envy of his fellows in bathing. The case as it now stands is an unanswerable argument in favor of a strictly aseptic mode of procedure, by which a cure has been made of a condition from arrest of development which I do not believe has ever before been attempted with success following.

Have any one of your readers known of such a case?

106 East Clayton Street, January 30, 1892.

THE HYGIENE OF THE HOLY COMMUNION.

By W. M. PARKER, M.D.,

MANCHESTER-BY-THE-SEA, MASS.

A recent item in the Medical Record concerning "The Communion and Prohibition," and one which has been copied into other medical journals, contains some points which are worthy of professional attention. I have been consulted professionally on the questions which have been raised in this connection, and I presume many others of the profession have had the same experience. The "temperance committee" of a certain parish called at my office and asked my advice and assistance in creating a sentiment against the use of wine at Holy Communion, stating that one young man for whom they were making efforts for his reform relapsed suddenly upon being present at the services on Communion Sunday—the strong smell of the wine fairly driving him to his "cups" again by creating a longing he could not overcome. They stated that very likely others were similarly affected throughout the country, which would make the practice one to be condemned. The statement in the Record seems to me to answer the objection: "While it is not exactly within the province of a medical journal to discuss purely theological questions, yet we cannot but wonder at the apparent lack of faith in a Christian minister, who can believe that anybody could be plunged into sin by doing what his religion commands him to do; for it is evidently the duty of a professing Christian to obey the precepts of his church."

Where a man is so weak that merely the smell of wine excites him to uncontrollable emotions, such a person should avoid the exciting cause and remain absent until his spiritual strength rose higher than his abnormal appetite. It would seem highly unjust to ask hundreds to forego the ceremonies of their religion to aid in securing temperance in one or two, and it is very doubtful, even if such a radical change could be made, that it would suffice! Perchance passing a drug store might suggest alcoholic odors, and then we might have requests to abolish drug stores! Where such a passion for drink exists and the patient cannot control his emotions he is certainly not cured, and he requires further treatment before it is expedient for him to mix freely in the affairs of normal life. The item referred to, having disposed of the question of prohibition, proceeds to discuss the hygiene of the Holy Communion as follows:

"But there is a medical side to the rite of Communion concerning which a word may be said. And that is the passing of the cup to a whole line of communicants for them to drink from, one after the other. There are certain diseases which are highly infectious, and which might readily be conveyed to the well by means of a cup moistened with the lips of others. We do not refer to syphilis only, although the danger of that must be apparent to all, for it is not every earnest Christian who has always been a Christian, or who has not at some time strayed from the narrow path; but there are other diseases the contagion of which may be spread in the same manner. In the Catholic Church this danger does not exist, and while desiring in no way to enter theological fields we believe that the Protestant churches might do well to consider, in these days of hygienic enlightenment, whether they acted wisely in departing from the ancient Catholic custom of giving the Communion in one kind only."

It seems to me very unfortunate for many reasons that this subject has come up for discussion in our medical journals, but it is no more than fair that, having arisen, the "other side" of the argument should be entitled to a hearing.

Some eight years ago I sent out circulars to prominent clergymen and medical men in this country and in Europe. Copies of these circulars were also published in our leading medical journals. The questions propounded were: 1, As to the danger from the use of the chalice or cup in the Holy Communion; 2, as to any precautions taken by the clergy to prevent contagion; and 3, whether any medical man knew of any case where disease of any kind had been acquired through contact with the cup in the celebration of the Eucharist. The result was I received a very large number of answers from medical men and clergymen of many different Protestant nations. An immense amount of professional opinion was received, but at the earnest solicitation of some clerical friends I abstained from making known the results of my investigations, lest even the mere discussion of the question might provoke statements likely to produce fear in the timid, or thought in others, which might detract from the solemnity of the ceremonies. In all this mass of professional experience and of carefully-prepared opinions, not one case could be found either in this country or in Europe where any injury had resulted of any kind whatever. While some admitted the possibility of danger, no one could produce a solitary instance casting suspicion upon the chalice as a source of contagion. One distinguished surgeon of New York City described a case of a wine merchant who tasted some wines he was sampling with a commercial traveller, and acquired thereby syphilitic infection. Here was contagion from one mouth to another through the medium of the wine-cup. The statement that "it is not every earnest Christian who has always been a Christian, or who has not at some time strayed from the narrow path," may be true enough, but I doubt very much if it happens, except under infinitesimally rare instances, that a syphilitic is present at the Holy Communion, and, if present, that it would be during the infectious state of the disease. Even the wife of such a patient is seldom in a condition to convey the poison through the slight contact of the lips with the chalice in the Holy Communion. Whether "the cup," which is so sacred, and which has been the greatest of all comfort to millions of people, needs at this late date to be brought under suspicion, is a question better left undiscussed.

There is so much of obvious importance awaiting needed investigation in sanitary science that the hygiene of the Holy Communion may be left to the wisdom of the ecclesiastical authorities, many of whom are singularly well versed in medical matters, and some of whom have taken high rank in the medical profession. With many sensible men, who have faith in God and in religion, the belief exists that if one leads a virtuous life he can attend to any or all the requirements of religion without danger of acquiring venereal disease thereby. We all know how many men seek to account for venereal infection by claiming almost impossible causes, and surely in this instance almost any physician's suspicion would be aroused by the statement, that disease had been acquired in the sacred ceremonies of religion. Surely it were better to inquire into the hygiene of the railway car and station water cups, and into the sanitary management of public places in general, as requiring our most urgent attention.

In the matter of precaution exercised by the clergy in the celebration of the Holy Communion a wide difference of opinion exists. In many of my correspondents I found a positive aversion to even think of such things at such a time, and as the greatest danger, especially in the Episcopal Church, falls upon the clergyman who consumes the last contents of the chalice, we can attain very little by discussion. Many clergymen wrote to me that it is their custom to continually turn the chalice as each communicant received, and when the circle had been reached to rapidly cleanse the rim of the cup with the purificator or small linen napkin held in the hand for that purpose. This surely would remove all vestige of dangerous mucus. It is greatly to the credit of those who practise this custom, when we consider the subject in the interest of hygiene, and it is to be hoped for the sake of those who may be timid, that this hygienic custom may be universal in Protestant churches, but for many such precautions would be highly unnecessary if not positively obnoxious. "It implies distrust," is the argument of some, "as to the cleanliness of the communicants." Such sensitiveness is also to be discouraged. A custom amounting almost to a rubric would be of great value in the management of the chalice during communion, and the use of a purificator, as already described. In the Roman Catholic Church this danger cannot exist, as the chalice is used only by the priests. I have been informed by a prominent physician of that church that for the very reason which we have been discussing the church had decided to withhold the chalice, but this has been denied to me by priests well versed in church history. Whatever the reason the fact remains the same, and this applies with equal strength when we assert that for a possible source of contagion we may utterly discard our searchings in the chalice for such unfortunate results.

We may safely believe that He who instituted the sacred feast will be equally strong to guard His children against such dreadful dangers. This is certainly not very much to ask of a believer, and those who do not believe are not likely to be recipients of the chalice and hence not exposed to any dangers which might possibly (?) lurk within or upon it! Communicants will be ready and willing to assume any dangers; indeed who does not know of cases where dangers of much greater magnitude have been gladly undergone for the pleasure and comfort found only in the Eucharist?

That hygiene can exert a useful influence in religion there can be no doubt, and this subject is even now attracting considerable attention, and I hope to be able to present a paper which is now in process of preparation very shortly. In considering a diagnosis of disease we find often very much to exclude, and surely the consideration of the contagion from the Holy Communion may be first and foremost.

February 14, 1892.

Freedom of Medical Practice in Germany.—A correspondent of the *Therapeutic Gazette* says that the German physician is absolutely unprotected by the Government since the introduction of Gewerbefreiheit (*i.e.*, trade-freedom, meaning liberty to carry on any trade or profession whatever). The government prosecutes all those carrying the title of "doctor" or "physician" illegally, but allows every barber or huckster to practise medicine.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, March 5, 1892.

SOME TRUTHS FROM AN ANCIENT SOURCE.

DR. FRANZ HARTMANN has written a book about Paracelsus, from which something can be learned. Dr. Hartmann is, we think, a little too credulous as to the character and attainments of Paracelsus, but it is pleasant to hear good of the dead, especially the four hundred years' dead.

Professor Paracelsus on one occasion remarked of his professional contemporaries as follows: "You have deserted the path of nature and built up an artificial system, which is fit for nothing but to swindle the sick. Your safety is due to the fact that your gibberish is unintelligible to the public, who fancy that it must have a meaning, and the consequence is that no one can come near you without being cheated. Your art does not consist in curing the sick, but in worming yourself into the favor of the rich, in swindling the poor, and in gaining admittance to the kitchens of the noblemen of the country. You live upon imposture, and the aid and abetment of the legal profession enables you to carry on your impostures and to evade punishment by the law. You poison the people and ruin their health."

Such observations would be likely to provoke unkindly feelings toward their author, especially as they had in them a large element of truth. It is not surprising that Paracelsus got a bad name from his contemporaries.

However, we wish rather to present what there was good or suggestive about the Doctor's ideas, rather than defend his character.

Paracelsus says: "There are three kingdoms acting in the constitution of man—an outer, an inner, and an innermost principle: namely, the external physical body; the inner (astral) man, and the innermost centre or God," and medicine correspondingly rests upon four pillars, which are: 1, *Philosophy, i.e.*, a knowledge of physical nature. 2, *Psychology, i.e.*, a knowledge of the powers of the mind. 3, *Alchemy, i.e.*, a knowledge of the divine powers in man, and 4, *The personal virtue* (holiness) *of the physician.*

The greatest and highest of all qualifications which a physician should possess is *Sapientia*, wisdom. Again, "he should be well experienced; for there are many kinds of disease, and they cannot be known without experience and learning. Every art requires experience. You cannot become a good painter, sculptor, or shoemaker by the mere reading of books, much less can you be a good physician without being experienced."

Quite as important it is that "a physician should exercise his art—not for his own sake—but for the sake of the patient; if he practises merely for his own benefit, such a physician resembles a wolf, and is even worse than an ordinary murderer; for while a man may defend himself against a murderous attack made upon him upon the high road, he has no means of defence against the murderer who, under the guise of a physician attacks him."

Surely, these are gospel truths to-day as they were in the sixteenth century.

Here is a pleasant observation for the specialist to take to heart: "He who wants to know man must look upon him as a whole and not as a patched-up piece of work. If he finds a part of the human body diseased, he must look for the causes which produce the disease, and not merely treat the external effects."

In the time of Paracelsus there were physicians who would now be called "dudes." Paracelsus did not like dudes. "I praise," he says, "the spagyric physicians; for they do not go about idling and putting on airs, being dressed in velvets and silks, having golden rings on their fingers and their hands in white gloves; but they are daily and nightly patiently engaged in their work in the fire and seeking their pastime within their own laboratory. They do not talk much or praise their medicines; for they know that the work must praise the master and not the master the work."

To our credit it must be admitted, we are mostly of the "spagyric" kind to-day.

Paracelsus had high ideals if he did not follow them, for he says: "One of the most necessary requirements for a physician is perfect purity and singleness of purpose. He should be free of ambition, vanity, envy, unchastity, pomposity, and self conceit, because these vices are the outcome of ignorance and incompatible with the light of divine wisdom which should illuminate the mind of the true physician. But our practitioners of medicine will not believe me when I say that it is necessary that a physician to be successful should be virtuous; because they imagine that success is due only to learning, and they cannot realize that all true wisdom and power is derived from God."

The ethics of Paracelsus, as may be seen, were of the highest kind His pathology was very nearly identical with the theosophy, homœopathy, and faith cure of to-day. He was essentially a spiritualist in his views of life and man.

The therapeutics of Paracelsus was also largely suggestive, and based on magnets, charms, and "sympathetic" substances. Salt, sulphur, and mercury were much used because of certain mystical theories entertained about them. An especially favorite tendency was the hypericum perfoliatum, which was said to be "almost a universal medicine."

We cannot now learn anything in practical therapeutics from Paracelsus.

HYDRIATRIC SKEPTICISM.

THERE is an idea gaining ground in this country that the external use of water is an excellent measure for promoting health and treating disease. This idea may become too much the vogue; and, at any rate, it is well to study each side of a question. In a recent discussion on the hygiene of the throat and nose, Dr. Allen, of Iowa, says (the *Post-Graduate*) that the people of his State bathe

but once a year, and yet they have a minimum death rate. Dr. William H. Porter, continuing the same discussion, thought that incessant bathing was in opposition to all physiological laws, and that the skin was too often looked upon as an excretory gland. If the term excretion of heat was used, then the integument and its glands might be considered as an excretory organ. If the term was used in the sense of removing waste products from the system, to call the skin an excretory organ was not only misleading but even quite erroneous. This is clearly shown by reference to the composition of the perspiration, which is said to be composed of 98.88 per cent. of water, 1.2 per cent. solid matter, and only 0.9 per cent. of the latter was represented by organic matter. Again, too much bathing mascerates the epithelial covering of the body and makes it unduly soft, while nature intended that the surface cells of the integument should dry and become a hard, protecting layer. This undue softening, against the dictates of nature, renders the surface layer much more liable to be knocked off and the underlying lymphatic opened, thus favoring the entrance of germs and toxic agents into the system.

Dr. Porter stated that he was firmly convinced that the daily bathing of infants was a very pernicious practice and sapped the vitality of many a child, causing puny, anæmic children, and very frequently resulted in an untimely death.

In regard to the cold plunge, it might also be opposed upon well-founded physiological laws, especially after increased tissue oxidization, for at that time the nervous system is usually in a state of partial exhaustion; to suddenly chill the surface of the body is apt to interrupt the physiological phenomena of the body and excite a condition simulating shock, with all its deteriorating influences. Athletes, according to Dr. Porter, rarely live beyond the age of thirty five, which seemed to be easily explained by the damaging effects of the cold plunge and the repeated shocks which the body is compelled to resist until the vital powers become permanently undermined.

The above assertions will come with something of a shock to the propagandists of water. Despite some truths regarding the physiology of the skin, we cannot at all accept the views Dr. Porter expresses so forcibly. While the skin is not normally an organ which throws off nitrogenous excreta, yet its activity is essential to the proper work of the kidneys. It is a supplementary excretory gland. Persons with a horny and functionless skin are liable to have renal disease, or some disorder of nutrition like diabetes.

It is better, indeed it is necessary, for man in a state of modern civilization to keep the functions of the skin at their best, and this is done with soap and water and friction.

THE INDICATIONS FOR AND RESULTS OF THE REMOVAL OF THE UTERINE APPENDAGES.

The *University Medical Magazine* of December, 1891, contains articles on the subject of the remote effects of the removal of the uterine appendages by Dr. Wharton Sinkler and Dr. Charles Carroll Lee. These articles are written in a judicial spirit, and present very fairly the opinions which medical men may and should hold at the present time, regarding the matter in question.

Dr. Sinkler first shows what the ordinary phenomena are that follow removal of the ovaries. These phenomena, as has long been known, resemble in many respects the changes of the climacteric. They consist of flushings and sweatings, which are very common, appear early and last with lessening intensity for two or three years. Disturbance of the heart's action, including rapid heart beat, is frequent; numbness and various parasthesiæ also appear. Patients may gain some flesh but they rarely get fat, contrary to a common belief. They do not necessarily have wasting of the mammæ, nor is there ever a change in voice or growth of coarse hair. The sexual appetite is not much changed for two or three years, but eventually tends to become lessened and abolished. Nervousness, irritability, and mental depression appear to be common, especially in women originally of a neurotic temperament. Insanity occurs undoubtedly in a certain percentage of cases, variously estimated at five or ten.

As to the effect of the removal of the appendages upon neuroses and psychoses, the consensus of opinion seems to be very decidedly to the effect that good is rarely accomplished and harm often done.

Very little, if any, trustworthy evidence is given to show that oöphorectomy is useful in insanity, although in the periodic menstrual form some successes are reported. As periodic insanities are of the psycho degenerative class, one must always expect a recurrence of the disease eventually. There is much evidence to show that, at least in neurotic persons, oöphorectomy tends to produce a condition of mental depression amounting often to melancholia.

In true epilepsy, even of a menstrual type, the operation is useless. In hystero-epilepsy, which many gynecologists seem to think is a form of epilepsy and not a form of hysteria, the removal of the ovaries is not a legitimate procedure. In certain forms of neurasthenia and hysteria minor, associated with decided pelvic trouble, the operation sometimes does good, but the results are slow, and the operation should not be attempted until every other measure has been carefully tried.

Dr. Lee's paper is a most candid and scientific presentation of the results of his own work. In the main his conclusions agree with that of others; but he does not find that removal of the ovaries produces the melancholic condition which has been observed by some.

The conclusions of Dr. Sinkler, which embody the main points given above, may be inserted here :

"The remote effects of removal of the ovaries and tubes upon the general health are, as a rule, to improve nutrition and to better the strength, especially if the operation has been done for diseased ovaries or pus-tubes.

"That excessive gain of flesh is rare, and that change of voice, growth of hair upon the face, and loss of feminine characteristics do not occur.

"That the sexual appetite in women is seldom changed by castration within two or three years after the operation, but after several years it becomes lessened.

"That it is often the case that after this operation patients are more nervous than formerly, and mental disturbances of various forms, insanity, and epilepsy, not infrequently follow it.

"That the influence of the operation is sometimes good upon insanity and epilepsy which are associated with severe dysmenorrhœa or occur periodically at the menstrual epochs; but when the insanity is constant, although it may be aggravated at the monthly periods, removal of the appendages is of no benefit. Hystero epilepsy is seldom permanently cured by the operation. Prolonged after treatment is generally necessary to relieve such cases.

"Local pain is often not relieved by the operation.

"Certain cases of neurasthenia which are associated with dysmenorrhœa, or with structural changes of the ovaries, are cured by the operation; nevertheless, no such case should be subjected to the operation without beforehand having the benefit of prolonged and patient treatment. It is unjustifiable to remove the ovaries and tubes in cases of neurasthenia, hysteria, etc., when these organs are healthy."

We trust that the general practitioner and ambitious gynecologists will both consider carefully the foregoing conclusions. They undoubtedly embody the experience of the profession, gained—at what a cost—during the past ten years.

A NEW STYPTIC.

The styptics ordinarily employed in medicine and surgery act by causing contraction of the blood-vessels, by increasing the coagulability of the blood, or lowering the action of the heart. While styptics fulfil the required conditions fairly well when locally applied, they are very uncertain agents when given internally. So far as increasing the coagulability of the blood is concerned, such substances as lead, gallic acid, and the ferric salts are of little value.

We read with some interest, therefore, the description given by Dr. A. E. Wright, in the *British Medical Journal* of December 19, 1891, of a new styptic which he asserts does undoubtedly increase the coagulability of the blood, both when used externally and internally. Dr. Wright's remedy consists of two substances, viz., the physiological ferment of the blood and certain salts of lime.

The fibrin ferment is obtained from the blood of herbivora, preferably the sheep, in the following way: The blood is received from the vessels into three times its volume of ordinary water. It is then set aside for a few minutes until it commences to gelatinize, when it is stirred in the ordinary manner with a bundle of sticks or of wires. The fibrin that is collected in this manner from the diluted blood is composed of very much finer threads than that prepared from the undiluted blood, and it also presents the advantage of enclosing much fewer blood-corpuscles. The fibrin thus obtained is washed out under a tap, or, better, in several changes of ordinary water until it is practically free from blood-pigment. This process of washing can usually be efficiently completed in the course of some ten minutes, and since the fibrin ferment is soluble in water it is expedient not to overdo the washing. The fibrin is now ready for use, and the fibrin ferment is to be obtained from it by extraction with a moderate quantity of water—approximately some five to ten volumes of water may be used to each portion of fibrin. The extraction is to be continued for some hours (I have usually extracted for twenty-four hours). The filtered extract constitutes fibrin ferment solution. To this is added one per cent. of calcium chloride.

Instead of proceeding immediately to the extraction of the fibrin ferment it is preferable to keep the fibrin ferment for a few days at least under strong alcohol (it may be left there practically indefinitely without loss of its property of yielding fibrin ferment). In such cases the alcohol must naturally be removed by either washing or pressing between filter-paper before proceeding to the extraction. If the extraction is now made with distilled water that has been boiled before using, there is evidently no difficulty in obtaining an aseptic fluid by this method.

The calcium chloride is added because it has been shown that its presence increases the coagulability of the blood. The mixture is to be applied locally. Its hypodermic injection in man is suggested but has not been tried.

Dr. Wright dwells more particularly upon the probable value of the internal use of calcium chloride alone. From experiments on dogs he shows that it apparently increases the coagulability of the blood. He suggests its use, therefore, in internal hemorrhages and in hæmophilia and aneurisms. The dose for a man is not given, but we infer that it must be large, *i.e.*, one or two drachms. It is to be regretted that Dr. Wright did not have the patience to make more practical tests of his styptic substances. They at least seem to be rational and safe.

News of the Week.

The Old New York Hospital.—The original charter granted by King George the Third to the New York Hospital was recently exhibited in court. It is written on four sheets of parchment, now yellow and faded; the seal, attached by a ribbon, resembles half a cracker. The most important history of medicine is covered by the life of this charter.

Mütter Lectureship of the College of Physicians of Philadelphia.—The next course of ten lectures, under the bequest of the late Professor Thomas Dent Mütter, M.D., LL.D., "On Some Point or Points Connected with Surgical Pathology," will be delivered in the winter of 1893–94 before the College of Physicians of Philadelphia. Compensation, $600. The appointment is open to the profession at large. Applications, stating subjects of proposed lectures, must be made before October 15, 1892, to William Hunt, M.D., Chairman of the Committee on the Mütter Museum, Thirteenth and Locust Streets, Philadelphia, Pa.

The National Popular Review is the name of a new illustrated monthly journal for professional and lay readers, devoted to preventive medicine. It will be under the editorial management of Dr Remondino, of San Diego, and its publication will begin in July next.

Dr. Harry Crumley, of Chattanooga, died of pneumonia in that city on January 25th. Dr. Crumley was born near Columbus, O., in 1859, and had been in practice in Chattanooga for five years.

Yellow Fever in Brazil.—Vessels coming from Brazilian ports continue to bring alarming reports of the yel-

low fever there, and on everyone that arrives several deaths among the crew have taken place during the voyage. Santos is the most afflicted of all the ports, and the disease has now assumed such virulence that even the natives and thoroughly acclimated residents are fleeing from the city. As long as frosty weather continues here there is little to fear, but as hot weather comes on unusual precautions will be needed to protect the city. It is hoped, however, that the epidemic will subside in Santos as the cooler weather approaches, and it is fortunate for us that as it grows hot here it becomes gradually cooler there. We are fortunate, also, in having an excellent quarantine service.

The Cancer Cure.—Dr. Adamkiewitz, of Cracow, who asserted some time ago that he had discovered a cure for cancer, and who has been experimenting in that direction in Vienna, recently presented, before the Vienna Medical Society, a patient whom he claimed to have cured of cancer. His assertion did not meet with a ready acceptance, however, Billroth and some others holding that it was more probable that a mistake in diagnosis had been made than that cancer had been cured. This is not a very scientific basis for scepticism, for it certainly ought to be possible to diagnose a cancerous tumor under the microscope with absolute certainty. The preparation that Adamkiewitz employs is used by injection, and is said to act only on the morbid growth. Its composition is as yet kept secret.

Small-pox is prevailing in severe epidemic form in Morocco, especially in and around Mellah.

High Temperature in Intermittent Fever. — Dr. Stephen Mackenzie reports in the *British Medical Journal* of February 13, 1892, the case of a patient in the London Hospital who was suffering from intermittent fever, whose temperature rose several times to 112° F. and over, the mercury registering on one day as high as 113 8° F.

Medical Education of Women in St. Petersburg. — The municipal authorities of St. Petersburg have voted a yearly grant of $7,500 to be used in promoting the medical education of women in that city.

Dr. Josef Hoffmann, of Vienna, died recently in that city at the age of sixty-eight. For eighteen years, up to 1887, he was director of the General Hospital in Vienna.

Twenty-three Deaths from Chloroform were reported in New South Wales during the six years ending with 1890.

Examinations for Marine Hospital Service.—A board of officers will be convened in Washington, May 2, 1892, for the purpose of examining applicants for admission to the grade of Assistant-Surgeon in the United States Marine Hospital Service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and the natural sciences. The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on the cadaver. Successful candidates will be numbered according to their attainments on examination and will be commissioned in the same order, as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After four years service, Assistant Surgeons are entitled to examination for promotion to the grade of Passed Assistant Surgeon. Promotion to the grade of Surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant Surgeons receive sixteen hundred dollars; Passed Assistant Surgeons, eighteen hundred dollars, and Surgeons twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty, or fifty dollars a month, according to grade, is allowed. All grades above that of Assistant Surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For further information or for invitation to appear before the board of examiners, address: Walter Wyman, Supervising Surgeon-General, M. H. S.

A Black List of Physicians.—The Medico-Ethical Association of Manchester, England, proposes to draw up a "black list" of medical practitioners in the neighborhood whose conduct seems objectionable to the members of the Association. All physicians whose mode of practice is, in the opinion of a committee of the Association, unethical and derogatory to the honor, interests, and welfare of the profession, will be considered eligible candidates for the band of the listed. It is to be hoped that the association has a good-sized fund on hand to meet the expenses of libel suits, and to pay occasional damages for defamation of character.

Sir George Edward Paget, Professor of Physic at Cambridge University, died on January 26th, in his eighty-third year. He was an elder brother of Sir James Paget.

Prohibition of Cocaine and Sulphonal.—According to an announcement in the *Medico Chirurgical Review*, of Constantinople, an imperial irade has been issued forbidding the use of cocaine and sulphonal throughout the Turkish dominions.

To Advance Medical Science.—The Boston *Medical and Surgical Journal* states that a bill has been introduced in the Massachusetts House of Representatives calling for the appointment by the Governor of a commission of five citizens, who shall be known as the Commissioners of Medical Science. It shall be their duty to convene at the call of the Governor and to give hearing to any matter brought before them which has to do with

any principle or system of principles looking to the practical advancement of medical science. The Governor and council are authorized by the bill to expend $5,000 for rewards to further the impetus of genius and research in the development of medical science.

A Concours will be held at Rush Medical College, of Chicago, beginning Tuesday evening, March 1st, for the purpose of filling the positions of Lecturer on Anatomy and on Materia Medica and Therapeutics in the Spring Faculty. The concours will consist of twenty-minute lectures, by each of the applicants, before the Faculty, students, and local profession, upon subjects pertaining to their branches, which will be furnished by professors of Anatomy and Materia Medica, and Therapeutics a week before the contest.

Students in German Universities.—The number of students matriculated this year in all the German universities is smaller by 891 than it was last year. A correspondent sends us the figures for each university, according to which we find that Berlin leads, with 5,527 students, Leipzig following with 3,431, and Munich coming third, with 3,292. The total number of students in the twenty-one universities is 27,841.

Prizes of the French Society of Hygiene.—Dr. Péan offers, through the Société Française d'Hygiène, of which he is the President, a prize consisting of one gold and two silver medals for the best essay on "Colonial Hygiene," dealing practically with the principles of hygiene which should guide the European living in tropical countries, as regards his dwelling, mode of life, clothing, food, and labor. Competing essays should be sent, before July 31st of the present year, to No. 30 Rue du Dragon, Paris. The subject for 1893 will be "Hygiene and Physical Education in Adolescence," serving as a supplement to three tracts already published on "Hygiene and Education in Childhood" (from birth to the age of twelve years). The essays should not exceed thirty-two octavo pages in length, and should be handed in before August 1, 1893.

Dr. William T. Lusk, of this city, was elected as honorary fellow of the Obstetrical Society of London at its meeting of February 3, 1892. Others elected at the same meeting were Sir Joseph Lister, Sir William Turner, of Edinburgh, and Dr. Carl S. F. Credé, of Leipsic.

The Health of Florence.—This city has long enjoyed the reputation of being exceedingly unhealthful and of having a very defective water-supply. Yet typhoid fever is not now at least very prevalent, as during the month of January of the present year there were but six deaths in the entire city and commune of Florence. The influenza there during the past winter was also of a very mild type.

The International Medical Congress of 1893.—The profession in Italy is sparing no pains to make this meeting as conspicuous a success as the best of its predecessors. At a recent sitting in Rome an organizing committee was formed, with Dr. Bacelli as its President; Professor Edoardo Maragliano, of Genoa, General Secretary; the Commendatore Professor Pagliani (head of the Public Health Department of Italy), Treasurer; and the Commendatore Signor Ferrando, steward (*economo*). There were also elected by ballot the heads of the fourteen sections over which the work of the Congress is to be distributed —to wit, Anatomy, Physiology, Clinical Medicine, Gynæcology and Obstetrics, General Pathology and Pathological Anatomy, Pharmacology, Surgery and Orthopœdics, Psychiatry and Neuropathology, Ophthalmology, Dermosyphilopathy, Legal Medicine, Hygiene, Laryngology and Otology, Naval and Military Sanitation. The committee is at this moment engaged in constituting local or subcommittees for the whole kingdom, to consist of the leading practitioners of every province. All this procedure is on the lines of the Berlin committee, which will also be imitated in giving to each provincial representative a distinctive badge, to be worn during the Congress. The committee, moreover, is proceeding to the election of foreign committees with a view to secure the presence at the Congress of the leading members of the profession in all parts of the world, so as to make the gathering as truly an international one as possible, worthy of its predecessors and worthy of Rome. The time of meeting has been fixed for September, the month in which the climate of Central Italy is at its best, when in Rome there is no risk whatever from malaria, and when the profession, particularly of Northwestern Europe, can best be spared from home.—*The Lancet.*

Dr. Alexander Lumnitzer, formerly Professor of Surgery at the University of Buda-Pesth, died recently at the age of seventy-one years. He had been an invalid for a number of years.

Dr. Castelo, one of the leading syphilographers in Madrid, has recently died.

Dr. Heinrich Rosenthal, editor of the *Allgemeine Medicinische Central Zeitung*, died of influenza, February 7th, in Berlin, at the age of fifty-eight years.

Secretary of Public Health.—Dr. Starling Loving, of Columbus, O., recently received a letter from Secretary Noble in which the writer expressed his sympathy with the movement looking to the creation of a department of public health whose head shall be a cabinet officer. "Individual effort," the letter said, "has done wonders in detecting the sources of danger to communities, and the discussion of such discoveries has interested every household. But liberal as the medical profession is and has, in our country, proved itself at all times to be, it is not fair or polite for us to leave it unsupported and nationally unrecognized. The international communication of intelligence that would follow the organization of a Bureau of Public Health would not only preserve our own inhabitants from many physical ills, but would greatly serve to strengthen the sympathy between all civilized peoples, who would correspond and co-operate with us. They would feel the same beneficent influences of the system we would realize."

A Death from Hydrophobia occurred recently in England. The victim was a boy of nine years who had been bitten by a rabid dog. He was sent to the Pasteur Institute in Paris and discharged as cured, but the disease developed in a few months and he died despite active treatment.

Reviews and Notices of Books.

Recent Materia Medica; Notes on Their Origin and Therapeutics. Fourth Edition. By F. Harwood Lescher, F.C.S.; Pereira Medallist; Commander of the Portuguese Order of Christ; Author of "The Elements of Pharmacy;" Auditor of the Pharmaceutical Society of Great Britain. Pp. 115. London: J. & A. Churchill. 1891.

Few works on materia medica keep stride with the progress in that branch of medicine. New drugs are being constantly put upon the market, and a large proportion of them are of great value. The work in hand, treating as it does solely of these new medicaments, is a necessary supplement to the Pharmacopœia and to the current works on materia medica. The necessary information concerning about four hundred drugs is given, including characteristics, therapeutics, dosage, etc. There is also a very complete therapeutical index.

A Manual of Venereal Diseases. Being an Epitome of the most Improved Treatment. By Everett M. Culver, A.M., M.D., Pathologist and Assistant Surgeon, Manhattan Hospital, New York City; Member of the American Association of Andrology and Syphilology, and late of the Department of Venereal Diseases of the Vanderbilt Clinic; and James R. Hayden, M.D., Chief of Clinic Venereal Department of Vanderbilt Clinic, College of Physicians and Surgeons, New York. Pp. 294. Illustrated. Philadelphia: Lea Brothers & Co. 1891.

The authors do all they profess to do, and do it well, too; that is to give a condensed working knowledge of the three venereal diseases: syphilis, gonorrhœa, and chancroid, avoiding all non practical points, such as history, statistics, unsettled questions, etc. The work is very concise; in fact, some subjects could have been very advantageously elaborated, but, on the whole, all that is necessary for diagnosis and treatment is given. The authors' connection with the Vanderbilt Clinic of New York has given them ample practical experience, and they write originally, giving the treatments which are in vogue at that clinic. These plans of treatment are adopted after long experimentation with all proposed treatments, and they are all excellent, if not the best. The book is a valuable one for the student and busy practitioner.

Burdett's Hospital Annual and Year-Book of Philanthropy, 1891–92. Edited by Henry C. Burdett. London: *The Hospital* (Limited).

This is a book of nearly six hundred pages, edited by one of the world's best authorities on hospitals. It is a guide to the British and colonial hospitals, dispensaries, nursing and convalescent institutions and asylums. Aside from this mass of useful material there are excellent chapters on the proper methods of conducting hospitals, their cost, plans of bookkeeping, etc. The book should be in the hands of all interested in hospitals, not only in Great Britain but in this country as well.

An Introduction to Human Physiology. By Augustus D. Waller, M.D., Lecturer on Physiology at St. Mary's Hospital Medical School. London: Longmans, Green, & Co. 1891.

This book is remarkable for originality, terseness, and style. It is an admirable text-book, and delightful and instructive reading. The old and the familiar acquire new graces in their present guise. Original drawings and diagrams abound, authorities for statements that denote wide research are everywhere given, and the work embodies the author's own special labors in the department of physiology. The usual elementary knowledge of anatomy, chemistry, and physics is presupposed, and Dr. Waller does not particularly concern himself with these, except to incline to a physical view of his subject, though in no narrow way. To the physician who is still a student, this "Introduction to Human Physiology" is of great value.

The Modern Treatment of Hip-Disease. By Charles F. Stillman, M.D. 12mo, pp. 118, with Sixty Illustrations. Physicians' Leisure Library, Series V. Detroit, Mich.: George S. Davis. 1891.

The volume considers only the mechanical treatment of hip-disease, and is compiled from publications and private letters of those surgeons whose original work is worthy of careful study. As few changes as possible have been made in putting this material into readable form. This little volume, which sells for twenty five cents, will be very welcome to those who lack the time or inclination to delve in theories and statistics, and who find no pleasure in long discussions upon traction and fixation.

Essentials of Bacteriology. By M. V. Ball, M.D.

It is a practical work for the beginner in bacteriological work, and the author has evidently taken the course of instruction given at the Hygienic Institute in Berlin.

Manual of Physical Diagnosis, for the Use of Students and Physicians. By James Tyson, M.D.

A short, concise manual, giving a clear outline of the methods of diagnosing pulmonary and cardiac lesions.

Leprosy. By George Thin, M.D. London: Percival & Co. 1891.

Within the last few years professional attention has been awakened to the extensive geographical distribution of leprosy, its redevelopment in countries from which it had almost completely disappeared, and its introduction into new countries which have hitherto enjoyed an immunity.
